Congenital Toxoplasmosis, Syphilis, Malaria, and Tuberculosis

MARIAN G. MICHAELS, PABLO SANCHEZ, AND P. LING LIN

KEY POINTS

- Maternal transmission of *Toxoplasma gondii* in the first trimester causes the greatest damage to the fetus, while infections later in pregnancy are more readily transmissible to the fetus.
- No neonate should be discharged from a birth hospital without documentation of maternal syphilis testing. If maternal syphilis testing is positive, the adequacy and timing of maternal treatment, comparison of neonate and maternal serologic test results, and the neonate's examination findings must be taken into consideration.
- Symptoms of congenital tuberculosis (TB) are protean but should be considered in any ill neonate whose mother is from a TB-endemic area.
- Symptoms of congenital malaria are nonspecific, though fever is universal. Parasitemia with *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae* has been reported with congenital malaria and should be considered in any infant whose mother is from a malaria-endemic region.

Congenital Toxoplasmosis

Epidemiology

Toxoplasmosis in the fetus and newborn is due to maternal infection with the parasite *Toxoplasma gondii*. This obligate protozoan parasite is ubiquitous in nature. While the cat is the definitive host, *T. gondii* can infect most warm-blooded animals. Human seroprevalence differs both geographically and by socioeconomic status. In the United States, seroprevalence studies obtained from the National Health and Nutrition Examination Survey 2009–2010 show a continuous decrease in seroprevalence, being around 9% for women of childbearing age, compared with prior surveys conducted from 1988–1994 and 1999–2004 (Jones et al., 2014). Accordingly, more than 90% of women of childbearing age in the United States are susceptible to primary infection with *T. gondii* during pregnancy with risk of transmission to the fetus. Seroprevalence is increased for those born outside the United States, living below the poverty level, and with a lower level of education. Global data on seroprevalence show the highest rates in Latin America, parts of eastern/central Europe, the Middle East, and parts of Southeast Asia and Africa (Pappas et al., 2009).

However, seroprevalence rates differ considerably from one country to another, from one region of a country to another, and even from one ethnic group to another in the same region. These widely disparate seroprevalence rates among different adult populations throughout the world have been explained by differences in eating and sanitation practices that contribute to acquisition of infection. Eating undercooked or raw meat or unwashed raw fruits and vegetables, drinking unpasteurized goat's milk, working with meat, having three or more kittens, and even certain climactic conditions have been associated with higher risks of infection (Jones et al., 2009). Waterborne transmission particularly from untreated well water has been noted (Jones et al., 2009; Krueger et al., 2014).

Older studies showed the prevalence of congenital infection in Massachusetts and New Hampshire to be 0.08 per 1000 births through immunoglobulin (Ig) M screening of newborn blood specimens collected on filter paper (Guerina et al., 1994). Higher rates of 310 per 1000 live births in Paris and Vienna have been noted, where maternal seroprevalence rates were approximately 70% and 40%, respectively. In Massachusetts, a case–control study involving 14 years of newborn screening for congenital toxoplasmosis found that the mother's birth outside the United States, particularly in Cambodia and Laos, and the mother's educational level and higher gravidity were strongly predictive of congenital infection (Jara et al., 2001). With approximately 4 million live births annually in the United States, there are an estimated 400–4000 babies born each year with congenital toxoplasmosis (Feldman et al., 2010).

Pathogenesis, Clinical Presentation, and Natural History

T. gondii exists in three forms:

1. An oocyst that is shed in cat feces from sporozoites formed within the cat's intestinal tract
2. A tachyzoite or endozoite that is the proliferative form and was formerly referred to as a *trophozoite*
3. A tissue cyst that has an intracystic form termed *cystozoite* or *bradyzoite*

Nonfeline mammals or birds ingest infective oocysts from contaminated soil. Tissue cysts then accumulate in the organs and skeletal muscle of these animals. The possible routes of transmission from animal to human are direct contact with infected cat feces, ingestion of undercooked meat containing infective cysts, and

ingestion of fruits or vegetables that have been in contaminated soil. Rarer methods of transmission can be from infected blood transfusions or organ transplantation (Schwartz et al., 2013). Congenital infection results from placental infection and subsequent hematogenous spread to the fetus.

Infection of the fetus occurs as a consequence of maternal primary infection during pregnancy or, rarely, just before conception (Villena et al., 1998b). Reactivation of latent *T. gondii* infection during pregnancy does not lead to fetal infection, except among immunocompromised women such as those infected with human immunodeficiency virus (HIV) or those undergoing chemotherapy (Langer, 1963; Mitchell et al., 1990; O'Donohoe et al., 1991; European Collaborative Study and Research Network on Congenital Toxoplasmosis, 1996; Dunn et al., 1997; Bachmeyer et al., 2006). Even under those circumstances the risk is low. Rarely, maternal reinfection can result in congenital toxoplasmosis (Hennequin et al., 1997). The severity of disease is related to both host and parasite factors as well as the stage of pregnancy (Jamieson et al., 2008; McLeod et al., 2012).

Infection of the fetus occurs transplacentally during maternal parasitemia. Placental infection is an important intermediary step, and up to 16 weeks may elapse between placental infection and subsequent infection of the fetus. This time delay has been termed the *prenatal incubation period* (Remington et al., 2001) and explains the success of intervention during pregnancy. Infections in twins show similar clinical manifestations in monozygotic twins, whereas discrepancies in clinical findings are common in dizygotic twins (Wiswell et al., 1984; Sibalic et al., 1986; Couvreur et al., 1991).

Overall, approximately 40% of infants born to mothers who acquired toxoplasmosis during pregnancy are congenitally infected with *T. gondii*. The rate of vertical transmission differs according to the trimester in which the mother became infected, with fetal infection rates increasing as pregnancy advances (Wong and Remington, 1994; Dunn et al., 1999; Remington et al., 2001). Only 15% of infants are infected when maternal infection occurs in the first trimester, whereas the transmission rates are 30% and 60% with maternal infection in the second and third trimesters respectively. The severity of clinical manifestations is greatest, however, when maternal infection occurs early in pregnancy. Maternal infection in the first trimester results in severe disease in as many as 40% of infected fetuses and in stillbirth or perinatal death in an additional 35% of infants (Wong and Remington, 1994). Conversely, maternal infection in the third trimester is rarely if ever associated with severe fetal disease or stillbirth, and approximately 90% of infants in such situations have subclinical infection (Wong and Remington, 1994).

Postnatally, transmission of *T. gondii* can occur from transfusion of blood or blood products or from transplantation of organ or bone marrow from a seropositive donor with latent infection. Although the organism has been detected in human milk, transmission by breastfeeding has not been documented.

Most newborns with congenital toxoplasmosis are asymptomatic, with apparent disease present in approximately 10%–25% of infected infants (Alford et al., 1969, 1974; Guerina et al., 1994), although thorough evaluation may demonstrate eye or neurologic abnormalities in approximately 20% of cases. The clinical manifestations of toxoplasmosis are often indistinguishable from those seen with other congenital infections, such as cytomegalovirus infection or congenital syphilis. Approximately one-third of infants have a generalized form of the disease that principally involves organs of the reticuloendothelial system. The abnormalities include temperature instability, hepatosplenomegaly, jaundice, pneumonitis,

TABLE 38.1 Clinical Findings Among Infants With Congenital Toxoplasmosis

| Finding | INFANTS WITH FINDINGS (%) | |
|------------------------------|--|--|
| | Neurologic Disease ^a (108 Cases) | Generalized Disease ^b (44 Cases) |
| Chorioretinitis | 94 | 66 |
| Abnormal cerebrospinal fluid | 55 | 84 |
| Anemia | 51 | 77 |
| Convulsions | 50 | 18 |
| Intracranial calcification | 50 | 4 |
| Jaundice | 29 | 80 |
| Hydrocephalus | 28 | 0 |
| Fever | 25 | 77 |
| Splenomegaly | 21 | 90 |
| Lymphadenopathy | 17 | 68 |
| Hepatomegaly | 17 | 77 |
| Vomiting | 16 | 48 |
| Microcephaly | 13 | 0 |
| Diarrhea | 6 | 25 |
| Cataracts | 5 | 0 |
| Eosinophilia | 4 | 18 |
| Abnormal bleeding | 3 | 18 |
| Hypothermia | 2 | 20 |
| Glaucoma | 2 | 0 |
| Optic atrophy | 2 | 0 |
| Microphthalmia | 2 | 0 |
| Rash | 1 | 25 |
| Pneumonitis | 0 | 41 |

^aInfants with otherwise undiagnosed central nervous system diseases in the first year of life.

^bInfants with otherwise undiagnosed nonneurologic diseases during the first 2 months of life.

Modified from Remington JS, McLeod R, Thulliez P, Desmonts G. Toxoplasmosis. In: Remington JS, Klein JO, Wilson CV, Nizet V, eds. *Infectious Diseases of the Fetus and Newborn Infant*. 7th ed. Philadelphia, PA: Saunders; 2011:918–1041.

generalized lymphadenopathy, rash, chorioretinitis, anemia, thrombocytopenia, eosinophilia, and abnormal cerebrospinal fluid (CSF) indices (Table 38.1; Eichenwald, 1960). The other two-thirds of infected infants principally manifest neurologic disease.

Central nervous system involvement is the hallmark of congenital *T. gondii* infection (Diebler et al., 1985; McAuley et al., 1994; Remington et al., 2001). Chorioretinitis, intracranial calcifications, and hydrocephalus are the most characteristic findings, occurring in approximately 86%, 37%, and 20% of symptomatic infants respectively (Eichenwald, 1960; Remington et al., 2001). This constellation of findings has been referred to as the *classic triad of congenital toxoplasmosis*; its presence should alert the clinician to the diagnosis. Intracranial calcifications may be single or multiple

but typically are generalized and located in the caudate nucleus, choroid plexus, meninges, and subependymal zone (Mussbichler, 1968); they also may occur periventricularly, as in cytomegalovirus infection. They are visualized best by computed tomography (CT) but are often detected on ultrasonography as well. Intracranial calcifications may resolve with appropriate antimicrobial therapy (McAuley et al., 1994). Hydrocephalus may be the only manifestation of disease; it results from the extensive periaqueductal and periventricular vasculitis with necrosis that causes obstruction of the ventricular system. Ventriculoperitoneal shunting is often required (Martinovic et al., 1982; McAuley et al., 1994). Abnormalities of the CSF are common; characteristically, they consist of lymphocytic pleocytosis and a markedly elevated protein content. Microcephaly, when present, indicates severe brain injury. Hypothermia and hyperthermia may occur secondary to hypothalamic involvement. *T. gondii* has been detected in the inner ear and mastoid, with the associated inflammation resulting in deafness. An ascending flaccid paralysis with myelitis has also been reported (Campbell et al., 2001).

Chorioretinitis secondary to congenital toxoplasmosis can manifest at any age. It usually manifests as strabismus in infants. Defects in visual acuity are more common in older children who had never received treatment. Typically the eye lesion consists of a focal necrotizing retinitis that is often bilateral with involvement of the macula and even the optic nerve. Complications include blindness, iridocyclitis, and cataracts (Arun et al., 2007; Phan et al., 2008).

Other less common manifestations of congenital toxoplasmosis are nonimmune hydrops fetalis, myocarditis, nephrotic syndrome, and Ig abnormalities, with both hypergammaglobulinemia and hypogammaglobulinemia described. Bony abnormalities consisting of metaphyseal lucencies similar to those seen in congenital syphilis have also been reported (Milgram, 1974). A variety of endocrine abnormalities may occur, including hypothyroidism, diabetes insipidus (Yamakawa et al., 1996; Oygur et al., 1998), precocious puberty, and growth hormone deficiency.

Diagnosis

Attempts to diagnose congenital toxoplasmosis are made either during pregnancy as part of a surveillance protocol because of maternal disease or abnormal fetal findings or after birth because of concern for infection. The test methods differ depending on the scenario and can be complicated. While commercial laboratories are able to perform some assays, reference laboratories are needed for more intensive evaluation and can be very useful with the availability of their consultative services, such as the Palo Alto Medical Foundation *Toxoplasma* Serology Laboratory (Palo Alto, CA, USA) (email toxolab@pamf.org, telephone 650-853-4828, <http://www.pamf.org/serology/>).

Serologic assays for measurement of antibodies to *T. gondii* in serum and body fluids are the most widely used methods of diagnosing toxoplasmosis in a pregnant woman and the fetus or newborn, but the findings can be difficult to interpret (Dannemann et al., 1990; Wong and Remington, 1994; Foudrinier et al., 1995; Naessens et al., 1999; Robert-Gangneux et al., 1999a; Villena et al., 1999; Boyer, 2001; Pinon et al., 2001; Madi et al., 2010). Most nonreference laboratories will be able to test for *Toxoplasma* IgG and IgM and perform polymerase chain reaction (PCR) assays. The more commonly used tests that detect *T. gondii*-specific IgG antibodies are the IgG enzyme-linked immunosorbent assay (ELISA), the indirect immunofluorescent antibody test, and direct

agglutination. The Sabin–Feldman dye test is considered the gold standard but requires live organisms and accordingly is performed by reference laboratories (Pomares and Montoya, 2016). If a pregnant woman is known to be seronegative before pregnancy and followed up serially, then these assays are useful to document seroconversion during pregnancy and risk to the fetus. However, most countries, including the United States, do not have routine prenatal screening, in which case it is important to decipher whether a positive test result represents recent infection or chronic infection without a risk to the fetus. Reference laboratories can perform a differential agglutination test that has been developed as a confirmatory test to differentiate acute from chronic maternal infection. This test compares the IgG serologic titer obtained with the use of formalin-fixed tachyzoites (HS antigen) with that obtained with acetone-fixed or methanol-fixed tachyzoites (AC antigen). The latter preparation contains stage-specific *T. gondii* antigens that are recognized by IgG antibodies only during early infection. An additional assay to assist in ruling out maternal infection acquired in the first 3 months of pregnancy is the IgG avidity test performed by the ELISA technique. This test is based on the principle that, although the antibody-binding avidity or affinity for an antigen is initially low after primary antigenic stimulation, IgG antibodies that are present from previous antigenic stimulation are usually of high avidity. Therefore a high-avidity result in the first trimester would exclude an infection acquired in the previous 12 weeks. Finally, an enzyme-linked immunofiltration assay has been developed that allows discrimination between IgG antibodies of maternal origin and IgG antibodies synthesized by the fetus as well as identification of antibody subtypes in infected neonates (Zufferey et al., 1999).

Tests that detect *T. gondii*-specific IgM include (1) the double-sandwich IgM ELISA, which has a sensitivity of 75%–80% and a specificity of 100% (Guerina et al., 1994), (2) the IgM immunosorbent agglutination assay, which is the most sensitive test but should not be performed on umbilical cord blood, because even small quantities of maternal IgM antibodies contaminating the specimen will yield a false-positive result, and (3) the IgM immunofluorescent antibody test. The last test is not recommended because it has a much lower sensitivity than either the IgM ELISA or the IgM immunosorbent agglutination assay, and it has poor specificity secondary to rheumatoid factors and antinuclear antibodies, contributing to false-positive results. Other tests used in reference laboratories include a *T. gondii*-specific IgA ELISA and IgA immunofiltration assay; a *T. gondii*-specific IgE immunofiltration assay; and IgG, IgM, and IgA immunoblotting tests, which are generally used in comparing samples from the neonate and the mother to help determine true infection. Interferon γ release assays (IGRAs) on infants have been used to diagnose congenital infection but are not available commercially (Pomares and Montoya, 2016).

PCR analysis has been used successfully to detect *T. gondii* DNA in amniotic fluid, placenta, CSF, brain, urine, and fetal and infant blood (Grover et al., 1990; Hohlfeld et al., 1994; Guy et al., 1996; Fricker-Hidalgo et al., 1998; Jenum et al., 1998; Foulon et al., 1999b; Romand et al., 2001). PCR performed on amniotic fluid obtained by amniocentesis is the preferred method of confirming in utero infection (Kasper et al., 2009). False-negative results have been reported, however, and interlaboratory variability in the performance of PCR assays has been documented (Guy et al., 1996; Romand et al., 2001). PCR performed on neonatal CSF is recommended for the evaluation of possible central nervous system (CNS) involvement.

Isolation of *T. gondii* from body fluids and tissues provides definitive evidence of infection. The organism can be isolated from placenta, amniotic fluid, fetal blood obtained by cordocentesis, umbilical cord blood, infant peripheral blood, and CSF by means of intraperitoneal and subcutaneous inoculation of laboratory mice (Wong and Remington, 1994; Foulon et al., 1999a; Remington et al., 2001). Mouse inoculation may require as long as 4–6 weeks for demonstration of the presence of the parasite. Although it is not a practical method, isolation of the organism should be attempted to confirm a diagnosis and is available (at the Palo Alto Medical Foundation *Toxoplasma* Serology Laboratory). In addition, tissue culture has been used to isolate *T. gondii* from amniotic fluid.

Histopathologic examination of the placenta and tissues obtained at postmortem examination or by biopsy from stillborns or infants should be performed because the specimens may demonstrate the presence of tachyzoites. In addition, tachyzoites have been demonstrated in CSF, ventricular fluid, and aqueous humor by specialized staining techniques.

Because most adults with acquired *T. gondii* infection are asymptomatic, evaluation of the pregnant woman and fetus is usually prompted by either seroconversion or an elevated maternal *Toxoplasma* species (spp.) IgG titer (Couvreur et al., 1988; Daffos et al., 1988; Montoya and Remington, 2008). The latter may reflect chronic past infection; therefore the acuity of the maternal infection is determined serologically with the HS–AC differential agglutination test, where agglutination titers to formalin-fixed tachyzoites (HS antigen) are compared with titers against acetone-fixed or methanol-fixed tachyzoites (AC antigen). In general, an acute pattern demonstrates high AC and HS titers, while a nonacute pattern demonstrates high AC titers and low HS titers. This method can differentiate an acute from a remote infection in pregnant women, whereas the levels of IgM and IgA antibodies detectable by ELISA or immunosorbent agglutination assay are elevated for prolonged periods. If recent maternal infection is documented by an acute pattern on the HS–AC test, seroconversion, or rising IgG antibody titers, the fetus should be evaluated by ultrasonography, and amniotic fluid should be tested for specific *Toxoplasma* spp. DNA with PCR. PCR has supplanted the need for cordocentesis, and a positive result confirms fetal infection (Hohlfeld et al., 1994). Postnatally, serologic testing of paired maternal and infant sera should be performed by a reliable laboratory that will include assays for *Toxoplasma* spp. IgG, IgM, and IgA antibodies (Pomares and Montoya, 2016). Waiting until the newborn is 10 days of age avoids contamination with maternal blood and false-positive IgM and IgA results. Subinoculation of mice with placental tissue, amniotic fluid, and umbilical cord blood should be considered. If the results of these tests suggest possible infection, the newborn should be evaluated fully with complete blood cell count and platelet determination, liver function tests, CSF evaluation (including tests for IgG and IgM antibodies and PCR) (Wallon et al., 1998), cranial ultrasound imaging or CT of the head, ophthalmologic examination, and hearing evaluation. The presence of neonatal IgM antibody in serum or CSF, or a positive PCR result for blood or CSF, indicates congenital infection. In addition, at-risk infants should undergo serologic follow-up to detect rising serum IgG titers during the first year after birth or persistence of IgG antibody beyond 12–15 months of age, when maternal IgG antibody has disappeared (Robert-Gangneux et al., 1999a, 1999b; Pomares and Montoya, 2016). Uninfected infants show a continuous decline in *T. gondii* IgG titer, which usually is gone by 7 months of age, with no detectable IgM or IgA antibodies.

With low IgG titers and an HS–AC differential agglutination test result that indicate remote maternal infection, further evaluation of the mother or infant is not necessary unless the mother is severely immunosuppressed. Because fetal infection has occurred during chronic *T. gondii* infection in very immunosuppressed women such as those with poorly controlled HIV infection, their infants should be evaluated serologically at birth for evidence of congenital infection. It has been suggested that HIV-infected pregnant women who have low CD4+ T-lymphocyte counts and who are seropositive for *T. gondii* antibody should receive prophylaxis to prevent fetal infection (Beaman et al., 1992; Wong and Remington, 1994). However, insufficient data are currently available to recommend that such therapy be given routinely for this indication. Nevertheless, if such women have had toxoplasmic encephalitis, prophylaxis with pyrimethamine, sulfadiazine, and leucovorin (folinic acid) should be considered (Masur et al., 2002).

Therapy

It is currently recommended that fetuses and infants younger than 1 year who are infected with *T. gondii* receive specific therapy effective against this congenital pathogen, even if they have no clinical signs of disease (Koppe et al., 1986; Couvreur et al., 1988; Daffos et al., 1988; Hohlfeld et al., 1989; McGee et al., 1992; McAuley et al., 1994; Wong and Remington, 1994; Roizen et al., 1995; Vergani et al., 1998; Foulon et al., 1999b; Friedman et al., 1999; Wallon et al., 1999; Gilbert et al., 2001; Peyron and Wallon, 2001; McLeod et al., 2009). On the basis of comparison with untreated historical controls, outcome is improved substantially by neonatal treatment. The effectiveness of maternal and fetal treatment is less clear. Spiramycin has been used in pregnant women with acute toxoplasmosis to reduce transplacental transmission of *T. gondii*. If fetal infection is confirmed after the 17th week of pregnancy, however, treatment with pyrimethamine, sulfadiazine, and folinic acid is recommended. Prenatal treatment of congenital toxoplasmosis is believed to reduce the clinical severity of infection in the newborn, while shifting the disease to a more subclinical form. This effect in turn may ameliorate the long-term neurologic complications that are commonly seen among infants who have clinical manifestations in the neonatal period. A metaanalysis of the effectiveness of prenatal treatment of toxoplasmosis infection found no evidence that such treatment significantly decreased clinical manifestations of disease in infected infants (SYROCOT Study Group, 2007). However, studies in Brazil and Germany suggest efficacy (Cortina-Borja et al., 2010; Hotop et al., 2012).

Neonatal treatment has resulted in reductions in sensorineural hearing loss and neurodevelopmental and visual handicaps. Table 38.2 shows the recommended guidelines for the treatment of congenital toxoplasmosis. In infants with congenital toxoplasmosis, the treatment consists of pyrimethamine, sulfadiazine, and folinic acid (McLeod et al., 1992; McAuley et al., 1994; Remington et al., 2001). The ideal duration of therapy is not known, although prolonged courses of at least 1 year are preferred. Currently most experts recommend combined treatment until the patient is 1 year old (Vergani et al., 1998; Villena et al., 1998a; Remington et al., 2001). Accessing pyrimethamine in the United States has recently become difficult because of extreme cost escalation. Assistance with access is available through <http://www.daraprimdirect.com> (telephone 1-877-258-2033).

Complete blood cell counts and platelet counts must be monitored closely while the patient is receiving therapy, because granulocytopenia, thrombocytopenia, and megaloblastic anemia

TABLE 38.2 Treatment Guidelines for Toxoplasmosis

| Condition | Therapy | Dose (Oral Unless Specified) | Duration |
|---|--|--|--|
| Pregnant woman with acute toxoplasmosis | Spiramycin for first 21 weeks of gestation or until term if fetus not infected ^a | 3 g, divided twice a day without food | Until fetal infection documented or excluded at 21 weeks; if fetal infection documented, replaced with pyrimethamine, leucovorin, and sulfadiazine |
| | Pyrimethamine (if fetal infection confirmed after 18th week of gestation or if infection acquired in last few weeks of gestation) <i>and</i> | Loading dosage: 100 mg/d in two divided doses for 2 days followed by 50 mg/d | Until delivery |
| | Sulfadiazine ^a <i>and</i> | 3 g per day (twice daily) | Until delivery |
| | Leucovorin ^b | 5–20 mg/d | Until delivery |
| Congenital <i>Toxoplasma gondii</i> infection in infant | Pyrimethamine <i>and</i> | Loading dosage: 2 mg/kg per day for 2 days; then 1 mg/kg per day for 6 months; then 1 mg/kg per day on Monday, Wednesday, and Friday each week | 1 year |
| | Sulfadiazine <i>and</i> | 100 mg/kg per day in two daily divided doses | 1 year |
| | Leucovorin ^b | 5–10 mg three times per week | 1 year |
| | Corticosteroids (prednisone) ^c | 1 mg/kg per day in two daily divided doses | Until resolution of elevated (≥ 1 g/dL) CSF protein level or active chorioretinitis that threatens vision |

^aDose may need to be adjusted for renal insufficiency.

^bMonitor blood and platelet counts weekly; adjust dosage for megaloblastic anemia, granulocytopenia, or thrombocytopenia.

^cWhen signs of inflammation or active chorioretinitis have subsided, dose can be tapered and eventually discontinued; use only in conjunction with pyrimethamine, sulfadiazine, and leucovorin. CSF, Cerebrospinal fluid.

Data from McAuley JB, Boyer KM, Remington JS, McLeod RL. Toxoplasmosis. In: Cherry JD, Harrison GJ, Kaplan SL, Steinbach WJ, Hotez PJ, eds. *Feigin and Cherry's Textbook of Pediatric Infectious Diseases*. 7th ed. Philadelphia, PA: Elsevier; 2014;2986–3005.

can occur. The counts usually increase once a higher dose of folinic acid is administered or pyrimethamine therapy and sulfadiazine therapy are discontinued temporarily. The indications for adjunctive therapy with corticosteroids such as prednisone (0.5 mg/kg twice per day) are a CSF protein concentration of 1 g/dL or higher and chorioretinitis that threatens vision; corticosteroid treatment is continued until either condition resolves. Current therapies are not effective against encysted bradyzoites and therefore might not prevent reactivation of chorioretinitis and neurologic disease.

Prognosis

Maternal toxoplasmosis acquired during the first and second trimesters has been associated with stillbirth and perinatal death secondary to severe fetal infection in approximately 35% and 7% of cases respectively. Among infants born with congenital toxoplasmosis, the mortality rate has been reported to be as high as 12%. In addition, infants with congenital toxoplasmosis are at high risk of ophthalmologic, neurodevelopmental, and audiologic impairments, including mental retardation (87%), seizures (82%), spasticity and palsies (71%), and deafness (15%) (Eichenwald, 1960; Koppe et al., 1986; Hohlfield et al., 1989; McAuley et al., 1994). Among neonates with subclinical infection, long-term follow-up reveals eye or neurologic disease in as many as 90% by the time they reach adulthood (Couvreur and Desmonts, 1962; Saxon et al., 1973; Wilson et al., 1980; Couvreur et al., 1984;

McLeod et al., 2000). While data from the US National Collaborative Treatment Trial show that severity is influenced by host and parasite factors, treatment of neonates with congenital toxoplasmosis early and for 1 year resulted in more favorable outcomes than were reported for untreated infants or infants who were treated for only 1 month (McLeod et al., 2006).

Prevention

Pregnant women whose serologic status for *T. gondii* is negative or unknown, as well as women who are attempting to conceive, should be educated on the prevention of congenital toxoplasmosis through avoidance of at-risk behaviors that may expose them to cat feces or encysted bradyzoites in raw meat (Wilson and Remington, 1980; Eskild et al., 1996; Lopez et al., 2000; Jones et al., 2001). Instructions to wear gloves when such women are changing cat litter boxes or gardening and to wash their hands after such activities should be given. Daily changing of cat litter will also decrease the chance of infection, because oocysts are not infective during the first 1–2 days after passage. In addition, keeping domestic cats inside and feeding them commercially prepared foods rather than undercooked meats or wild rodents reduce the likelihood of their becoming infected and capable of transmitting the infection to a pregnant woman. Oral ingestion of *T. gondii* can be prevented by either cooking meat to well done, smoking it, or curing it in brine and by washing kitchen surfaces and utensils that come into

contact with raw meat. Vegetables and fruits should be washed, and hands and kitchen surfaces should be cleaned after fruits, vegetables, and raw meat have been handled. Flies and cockroaches may serve as transport hosts for *T. gondii*, so their access to food must be prevented.

Routine serologic screening of women during pregnancy has been an effective means of prevention in France and Austria, where the incidence of congenital toxoplasmosis is high. No such screening is currently recommended in the United States. However, high-risk women, including those who are immunocompromised, should be screened early in pregnancy. Neonatal screening for IgM antibody has also been advocated so that asymptomatic infants can be detected and treated before neurologic symptoms develop (Petersen and Eaton, 1999). This strategy, however, has been hampered by the lack of readily available and reliable IgM test kits. Moreover, such screening will not detect the approximately 25% of infected infants who lack anti-*Toxoplasma* spp. IgM antibody. Further study involving cost analyses is needed to define the best preventive strategy for congenital toxoplasmosis in specific populations, regions, and countries.

Congenital Syphilis

Congenital syphilis, a result of fetal infection with the spirochete *Treponema pallidum*, remains a major public health problem worldwide. While adults acquire the infection sexually, infants are infected mostly in utero by a transplacental route or possibly during delivery by contact with a genital lesion of an infected mother. When maternal infection is detected during pregnancy, congenital syphilis is both preventable and treatable. However, if infected infants are not identified in a timely fashion, they may experience lifelong consequences. Accordingly, the Centers for Disease Control and Prevention (CDC) recommends that no mother or newborn be discharged from the hospital without the maternal serologic status for syphilis having been documented at least once during the pregnancy and preferably again at delivery if the mother is at increased risk or lives in a community with high prevalence of syphilis infection.

Epidemiology

The incidence of congenital syphilis mirrors the rates of primary and secondary syphilis in women. Overall, congenital syphilis disproportionately affects infants of black women whose prenatal care was lacking or inadequate. Less prenatal care has been associated with increased risk of fetal death that most often occurs by 31 weeks' gestation. From 1999–2013 in the United States, neonatal mortality secondary to congenital syphilis was 12 per 1000 live births, with a case fatality rate of 6.5%. Of the 418 reported deaths, 82% were stillbirths, and 89% of the mothers had untreated or inadequately treated syphilis (Su et al., 2016).

During the prepenicillin era of the 1930s and 1940s, 60–80 infants and children attended the congenital syphilis clinic of the Harriet Lane Home (Baltimore, MD) each week for arsenic therapy. Many more were lost to follow-up before completion of their 2–3-year course of treatment. It was unusual if fewer than three or four new cases were discovered in the general outpatient department in the course of 1 week. Subsequently, the frequency of congenital syphilis declined for several decades, only to increase dramatically in the late 1980s and early 1990s. This increase was fueled by the crack cocaine epidemic with women exchanging drugs for sex with multiple and anonymous partners. At the same time, in 1988, the CDC surveillance case definition for reporting cases of congenital syphilis was broadened to include all liveborn

• **Fig. 38.1** Congenital syphilis rate among infants younger than 1 year and the rate of primary and secondary syphilis among females 10 years or older. National Electronic Telecommunication System for Surveillance, United States, 2008–2014. CS, Congenital syphilis; P&S, primary and secondary. (Data from Bowen V, Su J, Torrone E, Kidd S, Weinstock H. Increase in incidence of congenital syphilis - United States, 2012–2014. *MMWR Morbid Mortal Wkly Rep.* 2015;64:1241–1245.)

and stillborn infants, irrespective of clinical findings, who had reactive serologic test results for syphilis and had been delivered to women with untreated or inadequately treated syphilis. This change resulted in a fourfold increase in reported cases of congenital syphilis when compared with the previously used Kaufman criteria that included only symptomatic infants (reviewed in *Centers for Disease Control*, 1989). For unclear reasons, the rate of maternal syphilis subsequently declined and the rate of congenital syphilis decreased from 1991–2005 but increased slightly from 2005–2008. From 2008–2012 the overall rate of congenital syphilis again decreased from 10.5 cases per 100,000 live births to 8.4 cases per 100,000 live births, reflecting decreasing trends in primary and secondary syphilis among women. However, in 2014, the rate of congenital syphilis increased across all regions of the United States, to 11.6 cases per 100,000 live births (458 cases), the highest rate reported since 2001 (Bowen et al., 2015) (Fig. 38.1).

Worldwide, congenital syphilis remains a major cause of fetal and neonatal death, with more newborns affected by congenital syphilis than by any other neonatal infection (Schmid, 2004). The World Health Organization estimates that globally, 1.5–1.85 million pregnant women are infected with syphilis annually, and half of them have neonates with adverse outcomes, such as stillbirth or prematurity in 17%–40%, congenital infection including nonimmune hydrops fetalis in 10%–30%, and death in 10%–23% (Gomez et al., 2013). The global burden of congenital syphilis is confounded further by the high prevalence of infection with HIV, as syphilis is a known risk factor for acquisition of HIV.

Pathogenesis, Clinical Presentation, and Natural History

The causative agent for syphilis is *T. pallidum*, a thin, corkscrew-shaped, flagellated, highly motile spirochete. *T. pallidum* is able to

invade the fetal compartment at any time during gestation, although the risk of fetal infection increases as the stage of pregnancy advances. Spirochetes have been detected in fetal tissue from spontaneous abortion as early as 9 and 10 weeks' gestation and recovered from amniotic fluid at 14 weeks of pregnancy by rabbit infectivity testing. Vertical transmission is related directly to the maternal stage of syphilis, with early syphilis resulting in significantly higher transmission rates than late latent infection. [Ingraham \(1950\)](#) reported that among 251 women with syphilis of less than 4 years' duration, 41% of their neonates were born alive and had congenital syphilis, 25% were stillborn, 14% died in the neonatal period, 21% had low birth weight but no evidence of syphilis, and 18% were normal full-term neonates. In contrast, only 2% of neonates born to mothers with late latent disease had congenital syphilis. [Fiumara et al. \(1952\)](#) reported that untreated maternal primary or secondary syphilis resulted in 50% of neonates having congenital syphilis, while the other 50% were stillborn, premature, or died in the neonatal period. With early and late latent infection, 40% and 10% of neonates, respectively, had congenital syphilis ([Fiumara et al., 1952](#)). These data are supported by a study in which mothers with primary, secondary, early latent, and late latent infection had transmission rates of 29%, 59%, 50%, and 13%, respectively ([Wendel, 1988](#)).

Because *T. pallidum* enters the fetal bloodstream directly, the primary stage of infection is completely bypassed. There is no chancre and no local lymphadenopathy. Instead, there is widespread hematogenous spread to all organs and tissues, including the liver, spleen, pancreas, intestine, kidney, skin, mucous membranes of the lips, nose, and anus, bones and cartilage, and the CNS. Invasion of the lung results in a characteristic "pneumonia alba" that is seen more frequently in developing countries.

Microscopically, the tissue alterations consist of interstitial fibrosis and perivascular inflammation with plasma and round cell infiltration, with visualization of spirochetes by silver or fluorescent staining. Gumma formation is infrequent in neonates, while extramedullary hematopoiesis involving the liver, spleen, dermis, kidneys, and other organs is common.

The placenta of neonates with congenital syphilis is often large, thick, and pale. Histopathologic features include villous enlargement, acute villitis, and erythroblastosis. Intense inflammation of the umbilical cord results in a "barber's pole" appearance where the edematous portions have a spiral striped zone of red and pale blue discoloration, interspersed with streaks of chalky white. Histologically, the umbilical cord exhibits abscess-like foci of necrosis within Wharton jelly and umbilical vessels. Placental and umbilical cord histopathology should be performed on every case of suspected syphilis.

The clinical, laboratory, and radiographic abnormalities of congenital syphilis are a consequence of active infection with *T. pallidum* and the resultant inflammatory response induced in various body organs and tissues. The severity of these manifestations is highly variable and can range from overwhelming involvement of multiple organs and body systems as occurs in nonimmune fetal hydrops to only laboratory or radiographic abnormalities. Most neonates born to mothers with untreated syphilis appear normal and have no clinical or laboratory evidence of infection at birth but may develop manifestations of disease several months to years later if left untreated. Two characteristic syndromes of clinical disease have been described. *Early congenital syphilis* refers to those clinical manifestations that appear in the first 2 years after birth, while those features that occur after 2 years and usually at puberty are designated as *late congenital syphilis*.

The signs and symptoms of early congenital syphilis are summarized in [Table 38.3](#). Prematurity and low birth weight is seen

TABLE 38.3 Clinical Features of Congenital Syphilis in the Neonatal Period

| Feature | Prevalence (%) |
|--|-----------------|
| Hepatomegaly with or without splenomegaly ^a | 60–100 |
| Radiographic bone changes (periostitis; osteochondritis); ^a pseudoparalysis of Parrot | 75–100; 12 |
| Lymphadenopathy | 20–50 |
| Jaundice | 50–70 |
| Rash ^a | 40 |
| Hepatitis (elevated transaminase concentrations) | 40 |
| Anemia and/or thrombocytopenia | 20–50 |
| Respiratory distress (pneumonia) | 34 |
| Fever | 10 ^b |
| Small for gestational age | 10 |
| Nonimmune hydrops | 5 |
| Rhinitis, mucous patch, condyloma lata, nephrotic syndrome, myocarditis, diarrhea (malabsorption), pancreatitis, chorioretinitis, cataract | Rare (<5) |
| Central nervous system (leptomeningitis, cranial nerve palsies, cerebral infarction, seizures, hypopituitarism) | Rare (<5) |

^aProminent feature.

^bMore common when presentation is at more than 3 weeks of age.

Data from Kollman TR, Dobson S. Syphilis. In: Remington JS, Klein JO, Wilson CV, Nizet V, eds. *Infectious Diseases of the Fetus and Newborn Infant*. 7th ed. Philadelphia, PA: Saunders; 2011:524–563; and Saloojee H, Velaphi S, Goga Y, et al. The prevention and management of congenital syphilis: an overview and recommendations. *Bull World Health Organ*. 2004; 82:424–430.

in 10%–40% of neonates ([Saloojee et al., 2004](#)). Hepatosplenomegaly is frequent, with extramedullary hematopoiesis a prominent finding in both the liver and the spleen. Approximately one-third of neonates have direct and indirect hyperbilirubinemia and elevated transaminase levels that may worsen transiently after initiation of penicillin therapy. Liver abnormalities may require months to resolve, but they rarely lead to cirrhosis. Generalized lymphadenopathy occurs in about 20% of infants, with characteristic enlargement of epitrochlear nodes. Anemia secondary to hemolysis or infection of the bone marrow with hematopoietic suppression may be severe ([Nolt et al., 2002](#)). Thrombocytopenia with petechiae and purpura occurs frequently and may be the sole manifestation of congenital infection. Other less common manifestations include ocular findings (chorioretinitis, cataract, glaucoma, and uveitis), pneumonitis, pneumonia alba, nephrotic syndrome, myocarditis, pancreatitis, and inflammation and fibrosis of the gastrointestinal tract leading to malabsorption and diarrhea.

Mucocutaneous lesions occur in 40%–60% of affected infants. The rash of congenital syphilis is usually oval and maculopapular but becomes copper colored with desquamation ([Fig. 38.2](#)) mostly in the palms and soles. A characteristic vesicular bullous eruption known as *pemphigus syphiliticus* may develop with erythema, blisters, and eventual crusting and skin wrinkling. Mucocutaneous junctions may also be involved, with the lips becoming weepy, thickened,

• **Fig. 38.2** Congenital Syphilis With Desquamation Over the Hand. (From American Academy of Pediatrics Committee on Infectious Diseases. Syphilis: clinical manifestations images. In: *Red Book Online Visual Library*. Elk Grove Village, IL: American Academy of Pediatrics; 2015. Available at <http://redbook.solutions.aap.org/chapter.aspx?resultClick=1&bookID=1484§ionID=88187246#91040951>.)

and rough. Radial cracks may traverse the vermillion zone surrounding the margins of the lips and are the beginning of the radiating scars called *rhagades* that are seen with late congenital syphilis. Rarely, mucous patches of the lips, tongue, and palate as well as white, flat, moist, raised plaques known as *condylomata lata* in the perioral and perianal areas may occur.

Rhinitis (“snuffles”), a watery nasal discharge that may become thick, purulent, and blood tinged, occurred in almost two-thirds of patients reported in the early literature but is now less prevalent (Ingall et al., 2006). Both the nasal discharge and vesicular fluid contain large concentrations of spirochetes and are highly infectious.

Bone radiographs demonstrate characteristic osteochondritis and periostitis in 60%–80% of infants with clinical signs of congenital syphilis and 20% of well-appearing, congenitally infected infants (Fig. 38.3). These abnormalities tend to involve the long bones (tibia, humerus, femur), ribs, and cranium and are usually symmetric, with the lower extremities involved more often than the upper extremities. Rarely, the bone lesions may be painful and result in subepiphyseal fracture and epiphyseal dislocation with pseudoparalysis of the affected limb (pseudoparalysis of Parrot). Osteochondritis involves the metaphysis and is visualized on the long bone radiographs approximately 5 weeks after fetal infection. There is metaphyseal demineralization with a radiolucent band representing a zone of osteoporosis below a radiodense band below the epiphyseal plate that is a widened and enhanced zone of provisional calcification. Radiographically, this results in the classic transverse saw-toothed appearance of the metaphysis, whose margins become serrated, jagged, and irregular. Bilateral demineralization and osseous destruction of the proximal medial tibial metaphysis are referred to as *Wimberger sign*. Periostitis requires 16 weeks for radiographic demonstration and consists of multiple layers of periosteal new bone formation in response to diaphyseal inflammation. After several months, complete healing of the affected bones occurs, even without antibiotic therapy.

CNS invasion by *T. pallidum* occurs in about 50% of infants with clinical, laboratory, or radiographic signs of congenital syphilis. Clinical signs of CNS involvement, however, are rare in the neonatal

• **Fig. 38.3** The radiograph displays the characteristic “celery stalking” and widening of the metaphyses in long bones found in untreated congenital syphilis. (From American Academy of Pediatrics Committee on Infectious Diseases. Syphilis: clinical manifestations images. In: *Red Book Online Visual Library*. Elk Grove Village, IL: American Academy of Pediatrics; 2015. Available at <http://redbook.solutions.aap.org/chapter.aspx?resultClick=1&bookID=1484§ionID=88187246#91040949>.)

period but can occur later if infected infants are not identified and treated (Nolt et al., 2002). Such manifestations include bulging fontanelle, seizures, leptomeningitis, cranial nerve palsies, hydrocephalus, cerebral infarction, and pituitary gland dysfunction with hypoglycemia and diabetes insipidus.

The clinical manifestations or stigmata of late congenital syphilis result from persistent inflammation or scarring associated with early congenital syphilis infection and are prevented by treatment during gestation or within the first 3 months of age. Infants with late congenital syphilis are not infectious. Late manifestations include dental stigmata such as Hutchinson teeth, where the permanent upper central incisors are small, widely spaced, barrel shaped, and notched, and mulberry molars, where the first lower molar has many small cusps instead of the usual four. Osteochondritis affecting the otic capsule may lead to cochlear degeneration and fibrous adhesions resulting in eighth nerve deafness, for which corticosteroid treatment may be beneficial. Late ocular manifestations include uveitis and interstitial keratitis. The constellation of interstitial keratitis, eighth cranial nerve deafness, and Hutchinson teeth is known as the Hutchinson triad.

The sequela of periostitis of the skull is frontal bossing, of the tibia is saber shins, and of the clavicle is Higouménakis sign with sternoclavicular thickening. Clutton joints, or painless synovitis and hydrarthrosis, are rare. The sequelae of syphilitic rhinitis include rhagades and a short maxilla with a high palatal arch. If the inflammation of the nasal mucosa extends to the underlying cartilage and bone, perforation of the palate and nasal septum occurs, resulting in a “saddle nose” deformity. Sequelae of CNS infection include mental retardation, hydrocephalus, seizure disorder, cranial nerve palsies, paralysis, and optic nerve atrophy (Fiumara and Lessell, 1970; Brosco et al., 2006).

Diagnosis

The diagnosis of congenital syphilis is established by the observation of spirochetes in body fluids or tissue and suggested by serologic test results. *T. pallidum* may be identified by dark-field microscopy, PCR testing, and fluorescent antibody or silver staining of

mucocutaneous lesions, nasal discharge, vesicular fluid, amniotic fluid, placenta, umbilical cord, or tissue obtained at autopsy. Its diagnosis, however, remains challenging since *T. pallidum* cannot be cultivated in artificial media, and many infected infants lack clinical, laboratory, and radiographic signs of disease. In addition, the diagnosis can often only be inferred since maternal nontreponemal and treponemal IgG antibodies are transferred transplacentally to the fetus, complicating the interpretation of reactive serologic test results for syphilis in neonates. A diagnosis of congenital syphilis is supported by an infant's serum quantitative nontreponemal antibody titer that is at least fourfold higher than the mother's titer. The absence of such a finding, however, does not exclude a diagnosis of congenital syphilis.

Serologic tests for syphilis are classified into nontreponemal and treponemal tests. Nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) test and the rapid plasma reagin test. The same nontreponemal test should be performed on the mother and the infant so that accurate comparisons can be made. Serologic testing of the infant should be performed on serum and not umbilical cord blood since false-positive test results have been reported secondary to contamination of the specimen with maternal blood or Wharton jelly. False-negative test results also may occur when the maternal nontreponemal titer is of low dilution (Rawstron and Bromberg, 1991). Measurement of total umbilical cord IgM levels and use of treponemal IgM ELISAs and the fluorescent treponemal antibody absorption IgM test have not proved useful in the diagnosis of congenital syphilis and are not recommended (Herremans et al., 2010).

Treponemal tests include the *T. pallidum* particle agglutination test, the fluorescent treponemal antibody absorption test, treponemal enzyme immunoassay (EIA), and chemiluminescence immunoassay (CIA). These treponemal tests are used to confirm the diagnosis of syphilis.

The diagnosis of congenital neurosyphilis is difficult to establish, with treponemal infection of the CNS only inferred from abnormalities of the CSF such as a reactive VDRL test result, pleocytosis (more than 18–25 white blood cells per microliter), and elevated protein content (>150 mg/dL; >170 mg/dL if infant is premature). However, a reactive CSF VDRL test result in neonates may be caused by passive transfer of nontreponemal IgG antibodies from serum into the CSF. By inoculation of rabbit testes with CSF, with resultant syphilitic infection of the rabbit, Michelow et al. (2002) found that invasion of the CNS with *T. pallidum* occurs in 41% of infants who have clinical, laboratory, or radiographic abnormalities of congenital syphilis and in 60% of those who have abnormal physical examination findings consistent with a diagnosis of congenital syphilis. The sensitivity and specificity of a reactive CSF VDRL test result, pleocytosis, and elevated protein content were 53% and 90%, 38% and 88%, and 56% and 78%, respectively (Sanchez et al., 1993). Therefore if clinical, laboratory, or radiographic evaluation supports a diagnosis of congenital syphilis, then therapy effective against CNS disease is warranted.

A practical approach to the evaluation and treatment of infants born to mothers with reactive serologic test results for syphilis is presented in Fig. 38.4. All pregnant women and their sexual partner(s) who have syphilis should be tested for coinfection with HIV, although infants born to mothers coinfecting with syphilis and HIV do not require different evaluation, therapy, or follow-up. In infants born to mothers with reactive serologic test results for syphilis, a serum quantitative nontreponemal test should be performed, and they should be carefully examined for physical signs of congenital syphilis. In neonates who have an abnormal physical

examination finding that is consistent with congenital syphilis, a serum quantitative nontreponemal serologic titer that is fourfold or greater than the mother's titer, or a positive dark-field or fluorescent antibody test result, or a positive PCR of lesions or body fluid(s), a complete blood cell count and platelet count should be performed as should CSF examination for cell count, protein content, and VDRL test result. Other tests, such as bone and chest radiographs, liver function tests, cranial ultrasonography, ophthalmologic examination, and evaluation of auditory brainstem response, should be performed as clinically indicated. These infants are considered to have proven or highly probable disease. Since spirochetemia with invasion of the CNS is likely, it is beneficial for follow-up purposes to establish CNS abnormalities at presentation.

In well-appearing neonates who have normal physical examination findings and a serum quantitative nontreponemal serologic titer that is equal to or less than fourfold the maternal titer, further evaluation and treatment depend on the maternal treatment history (see Fig. 38.4). If the mother has untreated syphilis or the treatment is undocumented or inadequate (<4 weeks before delivery or with any non-penicillin G regimen), a complete evaluation consisting of CSF analysis, long bone radiographs, and complete blood cell and platelet counts should be performed to guide optimal therapy. The evaluation findings must be completely normal if the infant is to be treated with a single intramuscular dose of benzathine penicillin G. Almost none of these infants will have CNS invasion by *T. pallidum* if their complete evaluation findings are normal. Alternatively, a complete evaluation is not necessary if 10 days of parenteral penicillin therapy is provided.

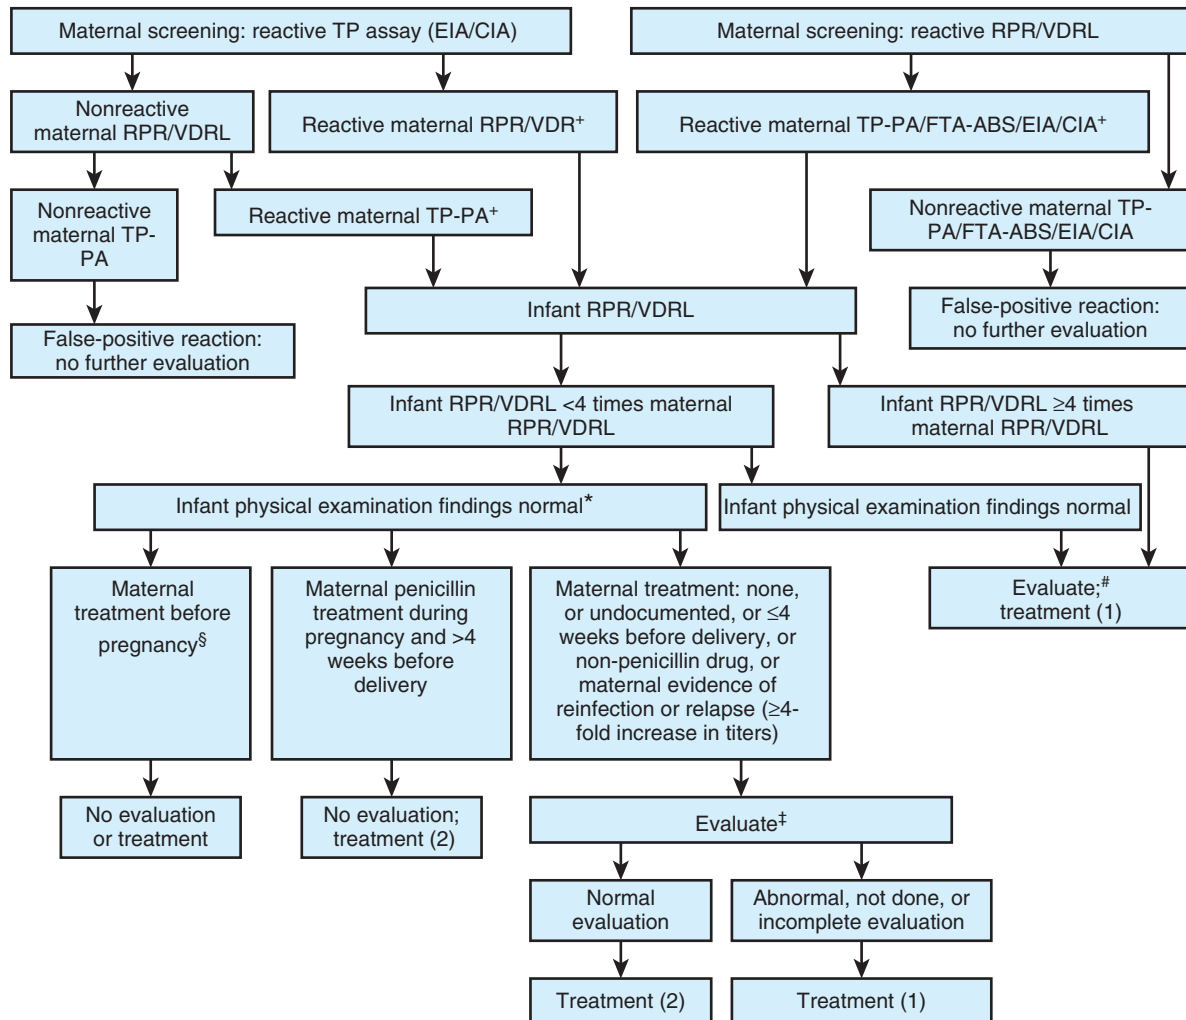

Treatment

Penicillin G is the only known effective antimicrobial agent for prevention of vertical transmission of syphilis and treatment of fetal infection and congenital syphilis. Pregnant women with syphilis should receive the penicillin regimen appropriate for the stage of infection, and if any dose of therapy is missed for latent syphilis, the full course of therapy must be repeated (Table 38.4). Pregnant women who have a history of penicillin allergy should be desensitized and treated with penicillin (Centers for Disease Control and Prevention, 2015b).

The decision to treat an infant for congenital syphilis is based on the clinical presentation, previous serologic test results and treatment of the mother, and the results of serologic testing of the neonate and mother at the time of delivery (Table 38.5, see Fig. 38.4). Infants with proven or highly probable disease, or who have normal physical examination findings but their evaluation findings are abnormal or their evaluation is incomplete, should be treated with either aqueous crystalline penicillin G (50,000 U/kg intravenously every 12 hours for the first week after birth, followed by every 8 hours beyond 7 days of age) or aqueous procaine penicillin G (50,000 U/kg intramuscularly once daily) for 10 days. If more than 1 day of therapy is missed, the entire course should be restarted. Data are insufficient regarding the use of other antimicrobial agents (e.g., ampicillin). When possible, a full 10-day course of penicillin is preferred, even if ampicillin was initially provided for possible sepsis.

Infants who have normal physical examination findings, CSF examination findings, complete blood cell and platelet counts, and long bone radiographs can be treated with a single intramuscular injection of benzathine penicillin G at a dose of 50,000 U/kg. If the risk of infection in these infants is substantial and adequate

Algorithm for Evaluation and Treatment of Infants Born to Mothers With Reactive Serologic Tests for Syphilis

+ Test for HIV antibody. Infants of HIV-infected mothers do not require different evaluation or treatment.

* If the infant's RPR/VDRL is nonreactive AND the mother has had no treatment, undocumented treatment, treatment ≤ 4 weeks before delivery, or no evidence of reinfection or relapse (≥ 4 -fold increase in titers), THEN treat infant with a single IM injection of benzathine penicillin (50,000 U/kg). No additional evaluation is needed.

§ Women who maintain a VDRL titer $\leq 1 : 2$ (RPR $\leq 1 : 4$) beyond 1 year following successful treatment are considered serofast.

Evaluation consists of CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL. Other tests as clinically indicated: long-bone X-rays, neuroimaging, auditory brainstem response, eye examination, chest X-ray, liver function tests.

‡ CBC, platelet count; CSF examination for cell count, protein, and quantitative VDRL; long-bone X-rays.

TREATMENT:

(1) Aqueous penicillin G 50,000 U/kg IV every 12h (≤ 1 week of age), q8 hr (> 1 week) or procaine penicillin G 50,000 U/kg IM single daily dose, x 10 days

(2) Benzathine penicillin G 50,000 U/kg IM x 1 dose

• **Fig. 38.4** Algorithm for evaluation and treatment of infants born to mothers with reactive serologic test results for syphilis. CBC, Complete blood cell; CIA, chemiluminescence immunoassay; CSF, cerebrospinal fluid; EIA, enzyme immunoassay; FTA-ABS, fluorescent treponemal antibody absorption; HIV, human immunodeficiency virus; IM, intramuscular/intramuscularly; IV, intravenously; RPR, rapid plasma reagin; TP, *Treponema pallidum*; TP-PA, *Treponema pallidum* particle agglutination; VDRL, Venereal Disease Research Laboratory.

TABLE 38.4 Recommended Treatment for Syphilis During Pregnancy

| Stage of Syphilis ^a | Drug (Penicillin) ^b | Route | Dose/Dosage |
|---|--------------------------------------|-------|--|
| Primary and secondary | Benzathine penicillin G ^c | IM | 2.4 million units in a single dose |
| Early latent (<1 year duration) | Benzathine penicillin G ^c | IM | 2.4 million units in a single dose |
| Late latent (>1 year duration) or latent syphilis of unknown duration | Benzathine penicillin G | IM | 2.4 million units weekly × 3 |
| Neurosyphilis and ocular syphilis | Aqueous penicillin G | IV | 3–4 million units every 4 h or continuous infusion for 10–14 days ^d |
| | or procaine penicillin G | IM | 2.4 million units once daily IM |
| | plus probenecid | | plus 500 mg orally four times a day, both for 10–14 days ^d |

^aPersons with human immunodeficiency virus (HIV) infection who have syphilis should be treated as those without HIV infection.

^bPregnant women who have a history of penicillin allergy should be desensitized and treated with penicillin.

^cFor women who have primary, secondary, or early latent syphilis, a second dose of benzathine penicillin G (2.4 million units IM) can be administered 1 week after the initial dose.

^dBenzathine penicillin G, 2.4 million units IM once per week for up to 3 weeks, can be considered after completion of 10–14 days of IV treatment.

IM, Intramuscular; IV, intravenous.

follow-up cannot be ensured, the 10-day course of aqueous or procaine penicillin is recommended by the CDC and American Academy of Pediatrics, regardless of the results of the CSF and laboratory examination. Failure of a single injection of benzathine penicillin G in the treatment of congenital syphilis has been reported. Treatment failures have been attributed to the inability of penicillin to adequately penetrate certain sites such as the aqueous humor and CNS and achieve treponemicidal concentrations in them.

Normal neonates born to mothers adequately treated during pregnancy and at more than 4 weeks before delivery should be considered as a “close contact” and receive a single intramuscular injection of benzathine penicillin G (50,000 U/kg), although no evaluation is required or recommended. Similarly, normal infants who have a nonreactive serum nontreponemal test result but are born to mothers with untreated or inadequately treated syphilis can receive a single dose of benzathine penicillin G intramuscularly without evaluation—an increasingly common scenario with the use of treponemal tests such as EIAs or CIAs for syphilis screening (“reverse sequence” screening).

During times of penicillin shortage when preparations of penicillin are unavailable, a 10-day course of ceftriaxone can be considered with careful clinical and serologic follow-up, including repeated CSF evaluation ([Centers for Disease Control and Prevention, 2015b](#)). Research efforts are needed to evaluate whether other antibiotics such as ampicillin can effectively treat CNS disease.

Within 24 hours of initiation of penicillin therapy, a small percentage of infants who are treated for congenital syphilis may develop a Jarisch–Herxheimer reaction, an acute inflammatory response likely caused by the rapid killing of spirochetes. It is characterized by fever, tachypnea, tachycardia, hypotension, accentuation of cutaneous lesions, or even death due to cardiovascular collapse. Treatment is supportive care.

Follow-Up

In infants with reactive serologic test results, serial quantitative nontreponemal tests should be performed every 2–3 months until the test results become nonreactive. In infants with congenital syphilis, nontreponemal serologic test values should decline fourfold, and the test results should become nonreactive within 6–12 months after appropriate treatment. Uninfected infants usually become seronegative by 6 months of age. Infants with persistently low, stable titers of nontreponemal tests beyond 1 year of age may require retreatment. A reactive treponemal test result beyond 18 months of age when the infant has lost all maternal IgG antibody confirms the diagnosis of congenital syphilis. Infants with abnormal CSF findings should undergo a repeated lumbar puncture performed 6 months after therapy. A reactive CSF VDRL test result or an abnormal protein content or cell count at that time is an indication for retreatment.

Prevention

Congenital syphilis is effectively prevented by prenatal serologic screening of mothers and penicillin treatment of infected women, their sexual partners, and their newborns ([US Preventive Services Task Force, 2009](#)). In all pregnant women a serologic test for syphilis should be performed at the first prenatal visit in the first trimester, with the test being repeated at 28–32 weeks' gestation and at delivery in areas with a high incidence of syphilis. Serologic screening tests should be performed on mothers and not on infants,

because the infant may have a nonreactive serologic test result, but the mother's test result may be reactive at a low level.

Although nontreponemal antibody testing has been recommended for antepartum syphilis screening, treponemal antibody testing (i.e., EIA or CIA) is being used increasingly by many laboratories as a cost-cutting measure for screening pregnant women (reverse sequence screening). If a treponemal EIA or CIA test is used for antepartum syphilis screening and the result is positive, a quantitative nontreponemal test (rapid plasma reagin test or VDRL test) should then be performed. If the nontreponemal test result is reactive, then a diagnosis of past or present syphilis is made, and the treatment of the mother and infant should be as discussed previously. However, if the nontreponemal test result is negative, then the results are considered discrepant and a second treponemal test (*T. pallidum* particle agglutination test is preferred) should be performed, preferably on the same specimen. If the second treponemal test result is reactive, current or past syphilis infection is confirmed. For women with a history of adequately treated syphilis, no further treatment is necessary. Women without a history of treatment should be staged and treated accordingly with a recommended penicillin regimen. If the second treponemal test result is nonreactive, then the positive EIA/CIA result is likely to represent a false-positive test result. The management of these infants is shown in [Fig. 38.4](#). Infants with suspected or proven congenital syphilis can be treated with standard precautions only. If there are cutaneous lesions or mucous membrane involvement, then gloves should be worn as well until 24 hours of treatment has been completed.

All cases of syphilis must be reported to the local public health department, which performs contact investigation and identifies core environments and populations. The public health impact of syphilis in pregnancy and infancy remains substantial, and only through optimal prenatal healthcare services will elimination of mother-to-child transmission of syphilis become a reality.

Congenital Malaria

Epidemiology

Malaria is a parasitic disease of epidemic proportion. An estimated 214 million new cases of malaria, with 438,000 deaths, were reported in 2015 alone ([World Health Organization, 2015d](#)). The greatest burden of disease occurs in the African region (88%), with Asia (10%) and the eastern Mediterranean areas (2%) also being affected. In areas of high transmission, death is concentrated largely among young children and pregnant women. In sub-Saharan Africa, malaria accounts for 10% of childhood deaths. Malaria is caused by four *Plasmodium* spp.: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*. Of these, *P. falciparum* is the major cause of morbidity and death. Humans typically acquire infection through the bite of the *Anopheles* spp. mosquito. Transmission may also occur through blood transfusion or vertically from the mother to fetus, resulting in congenital malaria ([Fig. 38.5](#)).

Congenital malaria occurs with all *Plasmodium* species. Among the 107 cases of congenital malaria reported in 1950 (mostly from Africa), 64% were caused by *P. falciparum*, 32% were caused by *P. vivax*, and 2% were caused by *P. malariae* ([Covell, 1950](#)). Although *P. falciparum* remains the predominant pathogen in sub-Saharan Africa, *P. vivax* may account for a larger proportion of cases in Asia. Among 27 cases reported in Thailand between 1981 and 2005, 82% were caused by *P. vivax* ([Wiwanitkit, 2006](#)). *P. malariae*

• **Fig. 38.5** Number of cases of congenital malaria reported to the National Malaria Surveillance System per year, 1966–2005. (From Lesko CR, Arguin PM, Newman RD. Congenital malaria in the United States: a review of cases from 1966 to 2005. *Arch Pediatr Adolesc Med.* 2007;161:1062–1067.)

is less frequently a causative agent, with fewer than 10 cases reported worldwide since 1950 (de Pontual et al., 2006). In China, *P. vivax* accounted for most (92.5%) of the 107 cases of congenital malaria cases reported (Tao et al., 2014). Concurrent infection with *P. malariae* and *P. vivax* has been documented (MacLeod et al., 1982). In the United States the predominant *Plasmodium* spp. causing congenital malaria reflects the countries of origin of the mothers. In Hulbert's (1992) review of 49 cases from 1950–1991, 82% of infections were caused by *P. vivax*. In the updated review in the United States reflecting 1966–2005, the predominant infecting species remained *P. vivax* (81%), although all four species were represented (Lesko et al., 2007).

The true rates of congenital malaria reported in the literature differ significantly depending on the time span reported, the method of reporting, and the clinical definition. Congenital malaria is commonly defined as the presence of *Plasmodium* spp. parasites in the peripheral blood during the first 7 days of life where the transmission occurs from the mother via placental transfer (Covell, 1950; Moran and Couper, 1999; Menendez and Mayor, 2007; Uneke, 2007a; Sotimehin et al., 2008). (There is an important distinction that the parasites are identified in the peripheral blood of the neonate and not the umbilical cord blood or placenta. While some have proposed use of umbilical cord blood as an alternative to peripheral blood, it does not represent active infection as is discussed later in this chapter.) In contrast, neonatal malaria is defined as the presence of *Plasmodium* spp. parasites in the peripheral blood between 7 and 30 days of life where mosquito transmission is the most likely cause. These definitions are most applicable in areas of high malaria transmission, where, among older infants, it would be difficult to distinguish congenitally acquired from mosquito-acquired disease. (This has been suggested by findings from Malawi, where approximately 50% of newborns with umbilical cord blood parasitemia were infected with parasites of a genotype different from that of the parasites that their mothers were infected at the time of delivery; Fischer, 2003.) Outside endemic areas, where postnatal transmission can be reasonably excluded, clinical

onset of disease often does not occur until after the first week of life, and age-specific criteria are not useful for the diagnosis of congenital malaria. It is likely that because of the delay in clinical presentation, many cases of congenital malaria in endemic areas were misclassified as being acquired from mosquitoes. Covell (1950) found the prevalence of congenital malaria among nonimmune populations (i.e., Europeans residing in or visiting endemic areas) to be approximately 7%. In other estimates before the 1970s, the prevalence of congenital malaria, defined as parasitemia detected in the first 7 days of life, was estimated to be 0.3% (16 of 5324 births) among immune mothers. Subsequent reports supported the observed low frequency of congenital malaria, defined as umbilical cord parasitemia or parasitemia in the first 24 hours of life, among indigenous populations (Bruce-Chwatt, 1952; Cannon, 1958; Williams and McFarlane, 1970; McGregor, 1984). These observations have been cited repeatedly in the literature to support the notion that congenital malaria is an uncommon occurrence in endemic areas despite the high prevalence of maternal and placental malaria.

In the last several decades, however, more in-depth studies of congenital malaria have suggested that it is far more common than initially reported, as rates from endemic and nonendemic areas ranged from 0.2%–47% (Obiajunwa et al., 2005; Desai et al., 2007; Menendez and Mayor, 2007; Enweronu-Laryea et al., 2013). Many have suggested that the low prevalence previously reported for congenital malaria was likely due to inadequate recognition and underreporting (Akindele et al., 1993; Ibhanesebhor, 1995; Fischer, 1997; Obiajunwa et al., 2005; Falade et al., 2007; Menendez and Mayor, 2007; Uneke, 2007b; Enweronu-Laryea et al., 2013). In Zambia during a season of heavy malaria transmission, incidence rates for congenital malaria ranged from 4%–15% (Nyirjesy et al., 1993). Congenital malaria, defined as neonatal parasitemia, was detected in 15.3% and 17.4% of neonates born in two sites in Nigeria (Mukhtar et al., 2006; Runsewe-Abiodun et al., 2006). The apparent increase in the frequency of congenital malaria has been attributed to increasing resistance of *P. falciparum* to

antimalarial drugs, resulting in increased maternal parasitemia, increased virulence of the parasite, and reduced transmission of antibody from the mother to the newborn because of malaria chemoprophylaxis administered to pregnant women. Meanwhile a multicenter trial in Nigeria showed an overall prevalence rate of 5% (range of 1.1%–11.5%) (Falade et al., 2007). The inconsistency may also represent true environmental differences with differences in levels of maternal immunity. It is clear that congenital malaria can exist in asymptomatic infants, which can make reporting in the literature even more variable (Mukhtar et al., 2006; Uneke, 2007a; Sotimehin et al., 2008).

Congenital malaria in nonendemic areas is rare. As of 1995, only 300 cases of congenital malaria had been reported in the literature (Balatbat et al., 1995), largely from outside malaria-endemic areas. In the United States the occurrence of congenital malaria is well documented because the country has been free of indigenous disease since the 1950s. From 1950–1991, 49 cases of congenital malaria were reported in the literature (Hulbert, 1992), and additional cases were reported during the next 15 years (Balatbat et al., 1995; Centers for Disease Control and Prevention, 2002; Baspinar et al., 2006). From 1966–2005, 81 cases of congenital malaria were reported to the National Malaria Surveillance System of the CDC (Gereige and Cimino, 1995; Starr and Wheeler, 1998; Viraraghavan and Jantausch, 2000; Lesko et al., 2007). Almost all the cases were among infants whose mothers were foreign born, suggesting that congenital malaria is primarily a health problem of recent immigrants rather than of US-born travelers to malaria-endemic countries. Forty-four women (54%) had emigrated from Asia, 27 (33%) from South America or Central America, and 7 (9%) from Africa. Until 1979, one to two cases were reported annually (Malviya and Shurin, 1984). An abrupt rise to 16 cases around 1981 (Fig. 38.6) correlated with an increase in the total number of cases of malaria that occurred as a result of a large influx of refugees and immigrants from Southeast Asia, with 15 of the 16 infants being born to mothers from that region (Quinn et al., 1982). In 2013 the CDC reported two cases of congenital malaria among the 1727 reported cases in the United States (Cullen et al., 2016). The lack of familiarity with this disease in the United States renders it a diagnostic and therapeutic challenge for clinicians, with delays in diagnosis potentially leading to significant morbidity and mortality (Griffith et al., 2007).

Natural History, Pathogenesis, and Clinical Presentation

Two key features play a critical role in the pathogenesis and natural history of congenital malaria:

1. Maternal and placental parasitemia
2. Existence of correlation between umbilical cord parasitemia and neonatal parasitemia

Pregnancy itself increases the risk of severe malaria, resulting in maternal–fetal detriment. Malaria also increases the risk of adverse pregnancy outcomes, including prematurity, abortion, and stillbirth. Despite major global health efforts, 28 million pregnant women were at risk of malaria in 2015 worldwide (World Health Organization, 2016). It is well established that both the frequency of disease and the density of parasitemia are higher in pregnant women than in nonpregnant women (Desai et al., 2007; Rogerson et al., 2007; Coll et al., 2008). Among 20 studies conducted between 1985 and 2000, the median prevalence of maternal malaria infection (defined as peripheral or placental infection) was 28% (Steketee et al., 2001). More recent studies of endemic areas within the last

• **Fig. 38.6** Age in weeks at symptom onset of infants with reported congenital malaria, United States, 1966 to 2005. (From Lesko CR, Arguin PM, Newman RD. Congenital malaria in the United States: a review of cases from 1966 to 2005. *Arch Pediatr Adolesc Med.* 2007;161:1062–1067.)

decade have reported significant geographic variation in the prevalence of malaria among pregnant women ranging between 8.1% and 52% (Raimi and Kanu, 2010; Mutagonda et al., 2016; Willilo et al., 2016). For this reason, it is widely contended that one in four pregnant women in areas of stable transmission in Africa have evidence of malaria infection at the time of delivery.

The clinical features of *P. falciparum* malaria in a pregnant woman depend to a large degree on her immune status, which in turn is determined by her prior exposure to malaria. Pregnancy itself suppresses both the humoral and the cell-mediated portions of the immune system, increasing the susceptibility to severe malaria. Impaired T-cell responses reduce systemic control of the infection and the ability to control liver-stage infections, resulting in relapse among some forms of *Plasmodium* spp. malaria (McLean et al., 2015). Primigravid women have a twofold to fourfold increased risk of placental malaria compared with multigravid women (McGregor, 1984; Desai et al., 2007; Uneke, 2008) that may be due to levels of antigen-specific *Plasmodium* spp. antibodies that appear to be boosted with successive pregnancies (McLean et al., 2015). In pregnant women with little or no preexisting immunity, such as women from nonendemic countries or travelers to malaria-endemic areas, infection is associated with high risks of severe disease, with significant maternal and perinatal mortality. In contrast, women residing in areas of stable malaria transmission usually have a high level of immunity to malaria. Infection may be frequently asymptomatic and therefore unsuspected or undetected, but it is associated with placental parasitization, with consequent effects on maternal and fetal outcomes. The most significant consequence of pregnancy-associated malaria is maternal anemia. It is estimated that in sub-Saharan Africa between 200,000 and 500,000 pregnant women develop anemia as a result of malaria and that up to 10,000 maternal anemia-related deaths are a consequence of *P. falciparum* parasitemia (Uneke, 2008). Malaria

in pregnancy also has potentially devastating effects on the fetus and newborn, including spontaneous abortion, stillbirth, premature delivery, congenital infection, and neonatal death (Fischer, 2003; Coll et al., 2008). In areas of high transmission in Africa, the risk of low birth weight approximately doubles if women have placental malaria, with the greatest effect in primigravidae (Desai et al., 2007). Pregnancy-associated malaria is believed to be responsible for 30%–35% of low birth weight infants and for 75,000–200,000 infant deaths each year (Coll et al., 2008).

The timing and mechanism of transmission of *Plasmodium* spp. parasites from the mother to the fetus are not well understood. Postulated mechanisms include maternal transfusion into fetal circulation either during pregnancy or at delivery or direct penetration of parasitized red blood cells through the chorionic villi or through premature separation of the placenta. (Transmission of malaria by breastfeeding is not known to occur.) *Plasmodium*-infected erythrocytes have the unique ability to undergo sequestration to the placenta, which may facilitate transmission to the fetus (Salanti et al., 2003; Rogerson et al., 2007). In utero transmission is supported by the finding of malarial parasites in fetal tissues at autopsy (Centers for Disease Control, 1981), by umbilical cord blood parasitemia (McGregor, 1984; Larkin and Thuma, 1991; Fischer, 1997), and by the onset of clinical signs of malaria within hours of birth (Covell, 1950; Brandenburg and Kenny, 1982; Gereige and Cimino, 1995). Vertical transmission of malaria probably does not occur as a result of transplacental passage of exoerythrocytic parasites. More likely, transmission occurs by transfusion of parasitized maternal erythrocytes through a breach in the placental barrier that may occur either prematurely during pregnancy or during labor.

The fate of the *Plasmodium* spp. parasite is unclear after it is transmitted to the fetus. Reinhardt (1978) found parasites in thick smears of umbilical cord blood in 22% of 19 infants born to women in Ivory Coast, but the peripheral blood smears were negative for parasites for all of the infants. Similarly, 4% of 1009 infants born to Tanzanian women had parasites in umbilical cord blood, but parasitemia was detected on peripheral smear in only 2 of 11 infants (McGregor, 1984). Parasitemia detected shortly after birth may also resolve without evolving into clinically symptomatic disease. The correlation between maternal, placental, umbilical cord, and peripheral parasitemia was evaluated in 1875 mother–baby pairs in Nigeria. Thick and thin blood smears were obtained within 4 hours of birth, and smear-positive (umbilical cord or peripheral) neonates were retested on days 2, 3, and 7 of life. Treatment was provided for those with symptoms or persistent parasitemia. The overall prevalence of congenital malaria was 5.1%, with parasitemia detected in 19% of neonates born to mothers with peripheral parasitemia, 21% of those born to mothers with placental malaria, and 45% of those with positive umbilical cord smear results. Spontaneous clearance of parasitemia occurred in 62% of neonates before day 2, whereas 33% were symptomatic within 3 days of birth (Falade et al., 2007). Depending on the region, spontaneous clearance of peripheral parasitemia has been documented in 87%–100% of neonates (Mukhtar et al., 2006; Lesko et al., 2007). Larkin and Thuma (1991) found peripheral parasitemia within 24 hours of age in 19 of 51 newborns (65%), but only 7 had clinical signs of disease. Because all 19 newborns received antimalarial therapy, it is unknown how many would have manifested disease if they had not been treated. The spontaneous clearance of *Plasmodium* spp. has been attributed to the protective effects of passive maternal antibody and weakened adherence to fetal hemoglobin (Amaratunga et al., 2011).

Infants with congenital malaria may be asymptomatic or can develop symptoms several weeks after birth. The clinical picture of overt congenital malaria is detailed in cases reported outside endemic areas (Harvey et al., 1969; Hindi and Azimi, 1980; Hulbert, 1992; Lesko et al., 2007). The manifestation of disease, although occasionally noted within hours of birth (Brandenburg and Kenny, 1982; Gereige and Cimino, 1995), is typically delayed until the infant is several weeks old. In the classic review of 49 infants with congenital malaria reported in the United States between 1950 and 1992, the mean age at onset of symptoms was 5.5 weeks, with 96% of infants presenting symptoms between 2 and 8 weeks of age (Hulbert, 1992). Among cases reported to the CDC from 1966–2005 (Lesko et al., 2007), the median age of symptom onset for 81 neonates was 21.5 days for all species combined (Table 38.6). Infants infected with *P. malariae* were significantly older at symptom onset (mean 53 days) compared with those infected with *P. vivax* or *P. falciparum*.

The prolonged interval between birth and onset of clinical manifestations may be explained by transmission late in pregnancy

TABLE 38.6 Frequency of Symptoms, Signs, and Laboratory Findings Among 81 Infants With a Diagnosis of Congenital Malaria (United States, 1966–2005)

| Symptoms, Signs, and Laboratory Findings | Infants ^a |
|--|----------------------|
| Fever | 70 (86%) |
| Anemia | 28 (36%) |
| Splenomegaly | 25 (31%) |
| Hepatomegaly | 16 (20%) |
| Thrombocytopenia | 12 (15%) |
| Jaundice | 11 (14%) |
| Irritability | 8 (10%) |
| Anorexia | 8 (10%) |
| Vomiting | 8 (10%) |
| Cough | 6 (7%) |
| Diarrhea | 3 (4%) |
| Lethargy | 3 (4%) |
| Hemolysis | 3 (4%) |
| Pallor | 3 (4%) |
| Hyperbilirubinemia | 2 (3%) |
| Failure to thrive | 2 (3%) |
| Seizures | 2 (3%) |
| Dyspnea | 1 (1%) |
| Purpura | 1 (1%) |
| Tachycardia | 1 (1%) |
| Monocytosis | 1 (1%) |

^aPercentages do not total 100% because each case can have more than one symptom, sign, or laboratory finding.

From Lesko CR, Arguin PM, Newman RD. Congenital malaria in the United States: a review of cases from 1966 to 2005. *Arch Pediatr Adolesc Med.* 2007;161:1062–1067.

TABLE 38.7 Reviews of Congenital Tuberculosis Cases Reported in the English-Language Literature in the Era of Chemotherapy

| Reference | Years Cases Reported | Number of Cases | Age at Clinical Presentation (Days) | Number of Infants With Reactive TST Results | Common Symptoms | Mortality (%) ^a |
|------------------------|----------------------|-----------------|-------------------------------------|---|---|----------------------------|
| Hageman et al. (1980) | 1952–1980 | 26 | NR | 2 of 14 | Respiratory distress, fever, hepatomegaly | 46 (12) |
| Cantwell et al. (1994) | 1980–1994 | 31 | Median 24 (range 1–84) | 0 of 9 | Hepatosplenomegaly, respiratory distress, fever | 38 (22) |
| Abughali et al. (1994) | 1952–1994 | 58 | NR | 1 of 19 | Respiratory distress, hepatomegaly, fever | 45 (14) |
| Laartz et al. (2002) | 1994–2002 | 16 | Mean 17.4 (range 1–60) | 1 of 4 | Respiratory distress, hepatomegaly, fever | 20 |

^aMortality with treatment is given in parentheses.
NR, Not reported; TST, tuberculin skin test.

or at delivery, such that multiple erythrocytic life cycles are required to produce clinically evident disease. Alternatively, the delay may be attributed to the presence of transplacentally acquired maternal antimalarial antibodies. When such antibodies are present in sufficient concentrations, as in infants born to immune mothers, parasitic replication can be prevented or attenuated, and clinical signs can be mild, delayed, or even absent. The presence of a high concentration of fetal hemoglobin in newborns may also promote resistance to multiplication of parasites. Among infants born to mothers with low or nonexistent immunity, parasitic replication is more likely uninhibited, and clinical signs of malaria may supervene. Preterm infants, who do not benefit from passive immunity, can manifest clinical signs earlier than full-term infants. In a review of premature neonates with congenital malaria, four of five neonates received a diagnosis in the first week of life (Ahmed et al., 1998), although the prompt medical evaluation afforded these neonates may have facilitated earlier detection.

The clinical features of congenital malaria are nonspecific and often resemble those of bacterial or viral sepsis and other congenital infections. Fever is almost uniformly present, although without the classic paroxysmal pattern described for malaria beyond the neonatal period. Hulbert (1992) noted fever in all 44 infants for whom clinical information was available. In the cases reported from 1966–2005, fever was reported in 70 of 81 cases (86%) (Lesko et al., 2007). Hepatomegaly and splenomegaly suggestive of a transplacentally acquired infection are found in a substantial portion of infants (Table 38.7). Anemia (often hemolytic), thrombocytopenia, and hyperbilirubinemia are the most commonly reported laboratory findings. Additional signs, symptoms, and laboratory findings are listed in Table 38.8.

In endemic areas the traditional belief has been that congenital malaria is rare and that when it occurs the infant is typically asymptomatic and develops no clinical features. The lack of symptoms has been attributed to transplacentally acquired antibodies from the mother as well as the protective effects of high levels of fetal hemoglobin. Falade et al. (2007) noted spontaneous clearance of parasitemia in 62% of 95 neonates before day 2 of life. Of the remaining neonates, 34% were symptomatic within 3 days of birth, with fever and refusal to eat being the most common signs of disease. When active surveillance for malaria was conducted in newborns being evaluated for possible bacterial sepsis in Nigeria, 16 of 203 neonates (8%) had parasitemia, and 10 (5%) met the definition of congenital malaria (Ibhanesebhor, 1995). Predominant

TABLE 38.8 Clinical Signs and Symptoms of Congenital Tuberculosis in 170 Infants

| Sign | Number of Patients | Percentage of Patients |
|---|--------------------|------------------------|
| Fever | 107 | 64.4 |

Modified from Peng W, Yang J, Liu E. Analysis of 170 cases of congenital TB reported in the literature between 1946 and 2009. *Pediatric Pulmonol.* 2011;46:1215–1224.

features of disease included fever, respiratory distress, anemia, and hepatomegaly. In another area in Nigeria, of 202 neonates younger than 1 week who were admitted for evaluation of sepsis, 71 (35%) received a diagnosis of congenital malaria (Ekanem et al., 2008). Fever was the most common symptom and was present in 93% of the neonates. Refusal to feed and jaundice were reported in approximately 33%. These observations suggest that, as in infants with diagnosed congenital malaria outside endemic areas, the clinical presentation of congenital malaria in endemic areas does not differ significantly from bacterial sepsis. Because the clinical symptoms

of congenital malaria may be indistinguishable from those of neonatal sepsis, it is suggested that screening for malaria be included as part of routine investigation of newborns with fever in areas of high malaria transmission (Runsewe-Abiodun et al., 2006; Ekanem et al., 2008).

Diagnosis

Diagnostic tests for malaria include blood smears, rapid antigen detection tests, and PCR. Definitive diagnosis of congenital malaria is based on the microscopic demonstration of parasites on stained thick and thin blood films. Thick blood smear films test for the presence of parasites by the concentration of red blood cells, whereas thin blood smear films allow species identification and quantification of parasitemia. In cases of suggested congenital malaria, specimens for smears should be obtained from both the infant and the mother. If the test results from the initial set of smears are negative, additional sets should be obtained every 12–24 hours; three sets are generally considered sufficient for diagnostic evaluation. Response to therapy may also be measured by clearance of parasitemia on blood films.

Rapid diagnostic tests (RDTs) are based on the immunochromatographic detection of parasite-specific antigens circulating in the bloodstream. Many RDTs are commercially available outside the United States, and, depending on the antigens targeted, the tests may detect only *P. falciparum* or all *Plasmodium* spp. RDTs are simple to use, do not require specialized training or facilities, and offer a useful alternative to microscopy in situations where reliable microscopic diagnostics are not readily available. However, the tests have demonstrated mixed results in multiple trials, and sensitivity remains a problem, especially at low parasite densities. To assure standard high-quality control among RDTs used worldwide, the World Health Organization has provided a laboratory-based evaluation to compare the performance of numerous RDTs used among malaria programs. (The minimum performance criteria are >90% sensitive, detection of at least 75% of low-density samples, false-positive rate of <10% and invalid rate of <5%.) In the most recent round of testing in 2014–2015, all products tested could detect high levels of parasitemia, but low parasite density (200 parasites per microliter) detection differed significantly (World Health Organization, 2015c). Information regarding the sensitivity of these tests is limited for neonatal or congenital malaria. Currently the World Health Organization recommends microscopy or malaria RDTs in all patients with suspected malaria before treatment is initiated.

The major advantage of PCR for the diagnosis of malaria is its ability to detect low-level parasitemia with species specification. Currently, PCR is used mainly to confirm positive blood smear tests, particularly when the results of the smear test are not definitive or there is a mixed species infection. PCR may detect DNA from circulating nonviable parasites after treatment, resulting in difficulty differentiating an active infection from a recently cleared infection. Currently, PCR is used only for epidemiologic research or survey mapping in endemic areas. Although PCR is a highly sensitive alternative to microscopy, the infrastructure and expertise required preclude its use in malaria-endemic areas and in many healthcare settings in the United States.

As with malaria in general, the diagnosis of congenital malaria outside endemic areas is often delayed because of nonspecific features and lack of clinical suspicion. Among the 81 cases reviewed by Lesko et al. (2007), a median length of delay of 8.5 days was noted for 15% of the infants. Occasionally the diagnosis is made incidentally. In all four cases of congenital malaria reported by Quinn

et al. (1982), *Plasmodium* spp. parasites were noted by hematology technicians on routine smear tests performed for blood cell counts. Maternal history of recent travel to or emigration from an endemic area may suggest the diagnosis but is often obscured by the lack of clinical or laboratory findings in the mother. Lesko et al. (2007) found that of the mothers for whom history was available, 67% reported having fever during pregnancy, and 26% reported a diagnosis of malaria during pregnancy. Maternal blood film tests were performed after either symptomatic illness or malaria diagnosis in the infant. Overall, parasitemia was detected in only 42% of women, although it is not clear whether an adequate number of smear tests were conducted for each patient. As a result, lack of peripheral parasitemia in the mother of an infant with suspected congenital malaria does not exclude the diagnosis.

Further confounding the early recognition of disease in the infant is the potentially prolonged lapse between malaria exposure in the mother and transmission of infection to the infant. *P. vivax* and *P. ovale* may remain dormant in the liver, especially if the infected individual did not receive therapy for the exoerythrocytic stage, which can cause a delayed relapse of malaria in travelers or immigrants. *P. malariae* can persist for 20–40 years before clinical symptoms or demonstrable parasitemia appear (Centers for Disease Control and Prevention, 2002). Congenital malaria has been reported in an infant whose mother lived in the United States for 5 years before delivery and had no signs or symptoms or malaria for more than 20 years (Harvey et al., 1969). In North Carolina, congenital *P. malariae* infection was reported in a 10-week-old infant who was born to a mother who had emigrated from the Democratic Republic of the Congo 4 years before delivery (Centers for Disease Control and Prevention, 2002). In a review by Lesko et al. (2007), the median duration from the mother's last exposure to delivery was 9.5 months. The time elapsed since exposure was longest for those with *P. malariae* infection, ranging from 2–12 years.

With recognition that congenital malaria is an exceptional occurrence in the United States, it is still important to include malaria in the differential diagnosis of fever in infants born to mothers who have been exposed to malaria, even if the exposure is remote and even if the woman is asymptomatic. Of 11 infants with congenital malaria in the United States born to women known to have parasitemia at or shortly after delivery, only five underwent testing by blood smears, and all five had negative test results at the time of delivery (Lesko et al., 2007). There are insufficient data to determine the overall risk of an infant developing congenital malaria when born to a woman at risk of parasitemia or identified with parasitemia at birth. Consequently, the evaluation of infants born outside endemic areas to women with epidemiologic risk factors for parasitemia should be individualized. In malaria-endemic areas, and as a public health measure, it has been recommended that blood smears should be checked as part of the evaluation of neonates with fever born to mothers who have had fever within a few weeks of delivery (Uneke, 2007a).

Treatment

The treatment of patients with malaria consists of supportive care and antimalarial therapy. Information regarding treatment of congenital malaria is limited, and the recommended chemotherapy is similar to that for noncongenital infections. The treatment regimen is based on the infecting species, the possibility of drug resistance, and the severity of the disease. For mild infections caused by *P. vivax*, *P. ovale* and *P. malariae* or chloroquine-sensitive *P. falciparum*,

chloroquine orally (10 mg base/kg initially followed by 5 mg base/kg 6, 24, and 48 hours later) is recommended. Treatment with primaquine is not necessary for congenitally acquired *P. vivax* or *P. ovale* infection because, like transfusion-associated malaria, congenital infection does not involve the exoerythrocytic phase (Del Punta et al., 2010).

The treatment of congenital malaria caused by chloroquine-resistant *P. falciparum* is poorly defined. In older children, three treatment options currently recommended are (1) orally administered quinine plus either tetracycline, doxycycline, or clindamycin; (2) atovaquone–proguanil; and (3) mefloquine. For the treatment of congenital malaria, oral administration of quinine sulfate and trimethoprim–sulfamethoxazole for 5 days was recommended by Quinn et al. (1982), who used the regimen to treat a 1-month-old infant. Ahmed et al. (1998) used a similar regimen for the treatment of an infant born at 28 weeks' gestation to a mother from Zaire. Quinine and clindamycin have been used for *P. falciparum* congenital malaria (Harrington and Duffy, 2008). Artemisinin-based combination treatments, such as dihydroartemisinin–piperaquine, can also be used in infants for treatment of malaria caused by drug-resistant *Plasmodium* spp. (Enweronu-Laryea et al., 2013; World Health Organization, 2015b). Other regimens used successfully in neonates include oral administration of quinine sulfate and pyrimethamine–sulfadoxine (Gerege and Cimino, 1995) and intravenous administration of quinine hydrochloride followed by oral administration of quinine (Airede, 1991). Intravenously administered quinine is no longer available in the United States. Because of the rarity of congenital malaria in the United States, the changing pattern of resistance, and the potential toxicity associated with drugs used for therapy, current treatment recommendations should be sought from the Malaria Branch of the CDC (<http://www.cdc.gov/malaria>). For healthcare professionals, assistance with management of malaria is also available 24 hours a day through the CDC Malaria Hotline (telephone 855-856-4713).

Severe malaria occurs most commonly with *P. falciparum* infection and is characterized by one or more of the following: (1) parasitemia with more than 5% of red blood cells infected, (2) CNS or other end-organ involvement, (3) shock, (4) acidosis, (5) severe anemia, or (6) hypoglycemia. Management of severe malaria involves parenteral treatment in an intensive care setting. Until recently the only parenteral therapy available in the United States was quinidine gluconate therapy. Quinidine is more cardiotoxic than quinine and should be administered with continuous cardiac monitoring. Artesunates can be given either intravenously or intramuscularly for 24 hours until oral medication can be tolerated, at which time combination therapy should be instituted (World Health Organization, 2015b). Exchange transfusion may be warranted when more than 10% of red blood cells are infected or if there are complications at lower parasite densities.

The efficacy of treatment should be monitored by examination of blood smears (i.e., malaria smears) every 12 hours until they are negative for malaria parasites. Response to therapy with chloroquine for non-*P. falciparum* malaria is usually favorable (Hindi and Azimi, 1980; Brandenburg and Kenny, 1982; Dowell and Musher, 1991). It has been suggested that neonates born to mothers with parasitemia at delivery should be treated presumptively for congenital malaria (Lesko et al., 2007). There are insufficient data to determine the risk of a neonate developing congenital malaria when born to a mother with parasitemia. Although there is evidence from endemic areas that parasitemia detected at or shortly after delivery may clear spontaneously, the clinical relevance

of this observation in nonendemic areas is unclear. It is recommended that physicians judge each case individually, considering factors such as access to medical care and reliability of follow-up in deciding whether to treat neonates presumptively.

Prognosis

Malaria during pregnancy is likely an underappreciated risk factor for increased infant morbidity and mortality in endemic areas. In a review of studies published between 1985 and 2000, a 3%–8% infant mortality rate was calculated on the basis of population-attributable risks for maternal malaria (Steketee et al., 2001). It was estimated that 75,000–200,000 infant deaths annually are associated with malaria during pregnancy, although what proportion of these are related to congenital malaria is unknown. Outside endemic areas, the short-term outcome of congenital malaria has been favorable. Most infants respond rapidly to therapy, with clearance of parasitemia. There were no reports of death or adverse outcomes in the 49 cases reported from 1950–1992 or in the 81 cases reported to the CDC from 1966–2005 (Hulbert, 1992; Lesko et al., 2007). It is unclear, however, whether the outcomes are due to an overall favorable prognosis or reporting bias.

Prevention

The prevention of congenital malaria is based on a pregnant woman's avoidance of exposure and use of chemoprophylaxis. The burden of malaria among pregnant women in endemic areas is well recognized, and prevention and control strategies for areas of high *P. falciparum* transmission aim at reducing maternal and infant mortality. The World Health Organization has proposed a three-pronged approach: (1) long-lasting insecticidal nets, (2) intermittent preventive treatment with an effective antimalarial agent in pregnancy, and (3) prompt diagnosis and effective treatment of malaria infection. In areas of moderate to high transmission of *P. falciparum*, this three-pronged intervention is strongly recommended, including intermittent preventive treatment with sulfadoxine–pyrimethamine. This drug is administered during prenatal care starting in the second trimester, at least 1 month apart, until the time of delivery (World Health Organization, 2014). A metaanalysis of more recent intervention trials suggests that successful prevention of these infections reduces the risk of severe maternal anemia by 38%, low birth weight by 43%, and perinatal mortality by 27% among paucigravid women (Desai et al., 2007). Unfortunately, the full implementation of prenatal malaria prevention efforts is burdened by the challenges associated with healthcare delivery in the developing world. In 2015, 15 million of the 28 million pregnant women at risk of malaria did not receive a dose of preventive medication (World Health Organization, 2015d).

Pregnant women originally from areas where malaria is endemic but who are now living in nonendemic areas may be only partially immune. When they travel to their countries of origin, they should be considered nonimmune and thus should receive the same recommendations as nonimmune women. For women in the United States, the CDC advises women who are pregnant or likely to become pregnant to avoid travel to areas with malaria transmission. If such travel is unavoidable, consultation with an infectious disease or malaria expert is advised. The use of mosquito netting, mesh screens on windows, insecticides, and mosquito repellents can decrease potential exposure to malaria parasites. For pregnant

women traveling to areas where there is no chloroquine-resistant *P. falciparum* malaria, prophylaxis with chloroquine is recommended. The safety of chloroquine for the fetus when used at the recommended doses for malaria prophylaxis is well established (MacLeod et al., 1982). For travel to areas where chloroquine resistance has been reported, mefloquine is the only medication that is currently recommended for prophylaxis during pregnancy. Use of atovaquone–proguanil during pregnancy was not associated with an increased risk of birth defects (Pasternak and Hviid, 2011); however, it is currently not recommended during pregnancy. Doxycycline is contraindicated because of adverse effects on the fetus caused by a related drug, tetracycline, which include dysplasia and discoloration of teeth and inhibition of bone growth. Healthcare professionals caring for women who cannot take the recommended antimalarial agent should contact the CDC Malaria Hotline (telephone 855-856-4713).

Congenital Tuberculosis

Epidemiology

Tuberculosis (TB) now equals HIV infection as a leading cause of death worldwide (World Health Organization, 2015a), and it remains one of the deadliest communicable diseases. One-third of the world's population is infected with *Mycobacterium tuberculosis*. In 2014, almost 10 million new TB cases were identified, and 1.5 million people died of the disease. The greatest burden of disease is in developing countries, where TB remains a major public health threat. While case rates have decreased in the United States and Europe, the rates have increased dramatically in the former Soviet Union, where public health efforts are impeded by political unrest, and in sub-Saharan Africa, where TB has been fueled by the HIV epidemic.

In the United States the incidence of TB declined steadily from 1953 through 1984, reaching a nadir of 9.4 cases per 100,000 people. The resurgence of disease was attributed to multiple factors, including the HIV epidemic, increased immigration, and a decline in public health funding for TB control. With the availability of antiretroviral therapy for HIV and fortification of public health measures, the epidemiologic trend was reversed. The overall incidence of TB in the United States has decreased dramatically since 1992 from 26,673 per 100,000 to only 9421 per 100,000 in 2014 (Centers for Disease Control and Prevention, 2016). Despite the decrease in the total burden of disease, TB continues to disproportionately affect the foreign-born and racial and ethnic minorities. In 2014, 66.5% of all cases of TB in the United States occurred in foreign-born persons (Scott et al., 2015).

The current epidemiology of tuberculosis in pregnancy is not well defined. Historical studies before the 1900s indicated that the severity of the disease was greater during pregnancy, though later reports appeared to contradict these early reports (Hedvall, 1953). With the resurgence of TB in the 1980s, the largest increase in the incidence of the disease occurred in the 25–44-year-old age group, and the number of cases among women of childbearing age rose by 40% (Cantwell et al., 1994). In 2014, nearly 40% of TB cases among women were in those of childbearing age between 15 and 45 years old (Centers for Disease Control and Prevention, 2015a). Thus women of childbearing age, especially those who are foreign born, and their newborns are at continued risk.

An estimated 1 million new cases of TB in children were identified in 2014 worldwide (World Health Organization, 2015a).

The prevalence of congenital TB is likely rare as fewer than 400 case reports have been published in the English-language literature. Most of the published cases were those in the prechemotherapy era (Laartz et al., 2002). Hageman et al. (1980) reported two cases of congenital TB and reviewed another 24 reported in the English-language literature since the introduction of isoniazid (INH) in 1952. In the subsequent decades, more than 34 additional cases of neonates with congenital TB have been described (Abughali et al., 1994; Cantwell et al., 1994; Manji et al., 2001; Mazade et al., 2001; Saitoh et al., 2001; Pejham et al., 2002; Grover et al., 2003; Laartz et al., 2002; Hatzistamatiou et al., 2003; Chen and Shih, 2004; Nicolaidou et al., 2005; Doudier et al., 2008; Mony et al., 2014; Hoyos-Orrego et al., 2015; Rosal et al., 2016; see Table 38.7). Most reports describe infants born in low-burden countries to mothers who have emigrated from high-burden countries. Although some reports originate from countries where TB is endemic, it is likely that congenital TB is underrecognized and underreported in these areas, largely because of the nonspecific clinical features of the disease and the limited diagnostic capability.

With increased global mobility and the epidemiologic trends of TB, it is likely that TB and congenital TB will continue to be observed in developed countries. The nonspecific features of congenital TB and the mortality associated with untreated disease underscore the importance of maintaining a high index of suspicion for TB in pregnant women and young infants.

Pathogenesis, Clinical Presentation, and Natural History

Transmission of *M. tuberculosis* from the mother to the neonate can occur in utero, during birth, or after birth. Although congenital infection is classically considered the result of in utero infection of the fetus, the term *congenital tuberculosis* has historically referred to infection acquired either in utero or during birth. The infection can be transmitted by direct spread to the fetus from the placenta via the umbilical vein or by aspiration/ingestion of infected amniotic fluid, either in utero or during birth.

Historically, congenital TB criteria were described by Beitzke (1935) to distinguish congenital tuberculosis from postnatally acquired TB. The criteria required that the infant have proven TB lesions and one of the following: (1) a primary hepatic complex as evidence of dissemination of the tubercle bacilli via the umbilical vein or (2) in the absence of a primary complex, the presence of tuberculous lesions in the first few days of life or the exclusion of postnatal infection by separation of the neonate at birth from the mother and other potential sources of infection. These criteria were developed before the introduction of chemotherapy, when infant mortality with congenital TB was high and diagnosis was largely based on autopsy findings. The demonstration of a primary hepatic complex with liver and regional node involvement requires an open surgical procedure; a percutaneous liver biopsy may demonstrate caseating granulomas, but the primary complex will seldom be identified. Given the impractical nature of such criteria, Cantwell et al. (1994) proposed a revised set of diagnostic criteria that became more applicable to current practice with increased diagnostic sensitivity. The neonate must have proven tuberculous lesions and at least one of the following: (1) lesions in the first week after birth, (2) a primary hepatic complex or caseating hepatic granulomas, (3) tuberculous infection of the placenta or maternal genital tract, or (4) exclusion or postnatal transmission by

thorough investigation of contacts. While the distinction between congenital TB and postnatally acquired disease may be relevant for academic or epidemiologic purposes, it does not affect the management, treatment, or prognosis of the disease.

The risk of congenital TB in infants born to women with TB is unknown but is likely low. Blackall (1969) reported only three cases among infants born to 100 mothers with TB. Ratner et al. (1951) identified no cases among infants born to 260 mothers with the disease. In a study of 1369 infants separated at birth from their tuberculous mothers and placed in foster care, only 12 became tuberculin positive during 4 years of observation, and in all 12 cases there was a source of infection in the postnatal environment (Cantwell et al., 1994). The low incidence of congenital TB is in part attributable to the high likelihood of infertility in women who have endometrial TB (Balasubramanian et al., 1999). However, in areas with high rates of TB transmission, TB in neonates may be undiagnosed or underreported, and the incidence of congenital infection or vertical transmission remains unknown.

Congenital TB is transmitted in one of three ways: (1) hematogenous spread from the infected placenta via the umbilical vein, (2) in utero aspiration or ingestion of amniotic fluid infected from the placenta or endometrium, or (3) ingestion of infected amniotic fluid or secretions from maternal genital lesions during delivery. In pregnant women, tuberculous bacillema can result in dissemination of infection to the placenta, the endometrium, or the genital tract. Hematogenous seeding and in utero aspiration likely account for most of the congenital TB cases, though actual sources are not well documented (Kaplan et al., 1980; Sosa et al., 2007; Abramowsky et al., 2012; Hoyos-Orrego et al., 2015). Several anecdotal cases of congenital TB have been reported in the literature associated with in vitro fertilization; in retrospect, tuberculous salpingitis was the likely cause of sterility (Zheng et al., 2014; Gleeson et al., 2015; Emiralioglu et al., 2016). While such events are likely to be associated with a very low frequency of congenital infection, they occur in more medically sophisticated areas that are likely to report them in the medical literature.

Tuberculous bacilli have been demonstrated in the decidua, amnion, and chorionic villi of the placenta (Abramowsky et al., 2012). It is unlikely that the fetus can be infected directly from the mother without the presence of a caseous lesion in the placenta, although massive involvement of the placenta does not always result in congenital TB. When a tubercle ruptures into the fetal circulation, bacilli in the umbilical vein can infect the liver, forming a primary focus with involvement of periportal lymph nodes. The bacilli may also pass through the liver and right ventricle and into the lungs, or they can enter the left ventricle via the foramen ovale and pass into the systemic circulation. The organisms in the lung remain dormant until after birth, when oxygenation and circulation result in their multiplication and the subsequent development of a primary pulmonary focus. Alternatively, if the caseous lesion in the placenta ruptures directly into the uterine cavity and bacilli infect the amniotic fluid, the fetus can inhale or ingest the bacilli, leading to primary foci in the lung, intestine, or middle ear. Pathologic examination of TB in the fetus and newborn usually demonstrates disseminated disease, with the liver and lungs being principally involved. Among 38 postmortem cases (Siegel, 1934), the lungs were involved in 97%, the liver in 82%, and the spleen in 76% of the infants. Other sites described are the gastrointestinal tract, kidneys, adrenal glands, and skin (Hageman et al., 1980; Agrawal and Rehman, 1995; Sood et al., 2000). It is not always possible to determine whether sites represent multiple primary

foci or are secondary to primary lesions in the lung or liver. The only lesion in the neonate that is unquestionably associated with congenital infection is a primary complex in the liver; all others may be acquired congenitally or postnatally.

M. tuberculosis infection acquired in utero or perinatally may be indistinguishable from postpartum infection. Postnatal acquisition of *M. tuberculosis* acquired by airborne inoculation, either from the mother or from another contagious adult in the newborn's environment, is the most common route of infection of the neonate. In addition, postnatal infection can occur from ingestion of infected breast milk from a mother with a tuberculous breast abscess. In the absence of a breast abscess, transmission of TB via breast milk has not been documented (Wang and Coonley, 1917).

The clinical manifestations of congenital TB are protean. Complications from TB during pregnancy include stillbirth, recurrent abortion, and infertility (Mittal et al., 2014). A retrospective cohort study from Mexico of neonates born to 35 mothers whose pregnancies were complicated by TB demonstrated an approximately twofold risk of prematurity compared with newborns of mothers without TB (Figueroa-Damian and Arredondo-Garcia, 2001). The manifestations of the disease resemble those of neonatal sepsis or other congenital infections. The affected neonate is commonly born prematurely (Davis et al., 1960; Foo et al., 1993; Amodio et al., 2005; Katumba-Lunyanya et al., 2005; Premkumar et al., 2008; Wanjari et al., 2008). Clinical signs may be evident shortly after birth but typically do not appear until 2–4 weeks of age (see Table 38.8). Among the 29 cases reviewed by Cantwell et al. (1994), the median age of presentation was 24 days. In an updated review of 16 cases reported since 1994, the mean age at presentation was slightly younger at 17.4 days (Laartz et al., 2002).

Before the availability of INH, congenital TB was almost uniformly fatal. Notable signs included failure to thrive, jaundice, and CNS involvement. In the post-INH era, the most commonly described features of the disease are respiratory distress, hepatomegaly with or without splenomegaly, and fever (Hageman et al., 1980; Abughali et al., 1994; Cantwell et al., 1994; Peng et al., 2011). Additional findings are listed in Table 38.8. Although it is important to evaluate an infant with suspected congenital TB for meningitis, CNS involvement occurs in less than 50% of cases (Hageman et al., 1980; Starke, 1997). Otitis media with aural discharge has been described as the presenting sign of congenital TB (Ng et al., 1995; Senbil et al., 1997), accompanied by regional lymphadenopathy (Gordon-Nesbitt and Rajan, 1973; Hatzistamatiou et al., 2003) or facial palsy (Pejham et al., 2002). It is presumed that the infection is due to the accumulation of infected amniotic fluid in the eustachian tube, either in utero or at birth. Cutaneous manifestations of congenital TB include papular, pustular, or vesicular lesions often surrounded by erythema (Loeffler et al., 1996; Sood et al., 2000; Al-Katawee et al., 2007). Biopsy of the lesions is often confirmatory, demonstrating granulomatous inflammation and the presence of acid-fast bacilli (AFB) on tissue stain (Hageman et al., 1980; Loeffler et al., 1996). A unique case of congenital TB involving the spine was reported in India (Grover et al., 2003).

Laboratory abnormalities among infants with congenital TB are also nonspecific but include leukocytosis (63.8%), thrombocytopenia (80%), elevated levels of inflammatory markers such as C-reactive protein (94.7%) or erythrocyte sedimentation rate (60.8%), and elevated liver enzyme levels (76.4%) (Peng et al., 2011).

Diagnosis

The timely diagnosis of congenital TB requires a high index of suspicion. Clinical signs of disease in the neonate are nonspecific, and disease in the mother may be unsuspected (as many cases are not diagnosed until the disease has been diagnosed in the neonate), contributing to further delay in diagnosis. The diagnosis of congenital TB should be considered in any neonate with suspected infection who is unresponsive to conventional antimicrobial therapy, especially when the mother is from a TB-endemic region. Evaluation for suspected disease should include a tuberculin skin test (TST), chest radiography, lumbar puncture, and mycobacterial culture of appropriate specimens. Biopsy specimens of affected tissue, either from the neonate or from the mother, and the placenta have been confirmatory in several case reports (Hageman et al., 1980; Abughali et al., 1994; Cantwell et al., 1994; Loeffler et al., 1996; Chou, 2002; Laartz et al., 2002).

The TST is the most commonly used diagnostic test for TB. The test uses five tuberculin units of purified protein derivative injected intradermally on the volar surface of the forearm. The reaction is measured 48–72 hours later as millimeters of induration. An estimated 10%–40% of immune-competent children with culture-proven TB do not initially react to a TST. Host factors such as young age and immunocompromised state can also decrease the sensitivity of the TST. Thus the TST cannot be used to exclude the diagnosis, and the findings must be interpreted in the context of each patient. Specificity of the TST may be compromised by cross-reactivity with bacille Calmette–Guérin vaccine or with environmental nontuberculous mycobacteria. The TST result is usually negative in neonates with congenital or perinatal TB, either secondary to immature cell-mediated immunity or because of overwhelming disease. Hageman et al. (1980) found that only 2 of 14 infants who underwent skin testing had positive test results; on repeated testing, seven infants subsequently demonstrated positive TST findings, the earliest being at 6 weeks of age, almost 4 weeks after presentation with clinical signs. Similarly, the results of TSTs performed in 9 of 29 patients described by Cantwell et al. (1994) were all negative, with the results of subsequent testing being positive in two of the nine infants. Among the 16 infants with congenital TB reviewed by Laartz et al. (2002), three of four infants tested had nonreactive TST results.

Recent advances in diagnostic tools for TB include whole-blood IGRAs, which are immunologically based tests that measure interferon γ production from lymphocytes in response to antigens that are fairly specific to *M. tuberculosis*. The two types of assays currently available are the Quantiferon Gold (Cellestis, Valencia, CA, USA) and the enzyme-linked immunosorbent spot assay commercially known as the T-Spot.TB (Oxford Immunotec, Abington, United Kingdom). The advantages of these tests include lack of cross-reactivity with bacille Calmette–Guérin vaccine and most nontuberculous mycobacteria. However, the correlation between the findings of IGRAs and TSTs is variable, and negative results do not definitively exclude TB. Moreover, published experience with the use of IGRAs in children is limited, and the negative predictive value of these tests in this population is unclear. Although IGRAs are endorsed by the CDC for use in circumstances in which a TST is indicated (Mazurek et al., 2010), the tests are not approved for use in children younger than 5 years (Starke and Committee on Infectious Diseases, 2014). There is, however, growing experience with these assays, and many experts in the pediatric infectious disease field have used the IGRAs in children aged between 2 and 4 years (Starke and Committee on Infectious Diseases, 2014). The

• **Fig. 38.7** Miliary Tuberculosis in a Neonate With Congenital Tuberculosis. (From Singh M, Kothur K, Dayal D, Kusuma S. Perinatal tuberculosis a case series. *J Trop Pediatr.* 2007;53:135–138.)

sensitivity of IGRAs in children younger than 1 year is reduced compared with that in adults (Nicol et al., 2009), and data on the use of IGRAs in newborns are limited to case reports (Connell et al., 2006; Zheng et al., 2014; Sun et al., 2015). While more immunologically advanced IGRAs are being tested and should overcome these limitations, these assays should not yet be substituted for TSTs in the evaluation of congenital TB.

Given the frequency of respiratory distress in infants with congenital TB, it is not surprising that chest radiographs are frequently abnormal at the first examination. In a metaanalysis of 170 infants with congenital TB between 1946 and 2009, 93.1% of all infants had an abnormality on the chest radiograph. Among the 29 cases reviewed by Cantwell et al. (1994), 23 infants (79%) had chest radiograph abnormalities, most being nonspecific infiltrates. Miliary disease was the most common specific radiographic characteristic (46.8%) (Fig. 38.7), followed by multiple pulmonary nodules (11.1%), lobar pneumonia (11.8%), bronchopneumonia (9.7%), and interstitial pneumonia (9%). Cavitation secondary to progressive pulmonary involvement has been reported (Cunningham et al., 1982). Mediastinal adenopathy was also reported in 9.7% of infants. CT of the chest may demonstrate adenopathy suggestive of TB or confirm miliary disease (Singh et al., 2007; Das et al., 2008). An ultrasound or CT image of the abdomen may reveal enlargement of the liver, spleen, or both, possibly with areas of abscesses (Senbil et al., 1997; Grover et al., 2003; Berk and Sylvester, 2004; Amodio et al., 2005), necrotic retroperitoneal or intra-abdominal lymphadenopathy, or ascites (Peng et al., 2011). Spinal disease associated with congenital TB was identified by radiograph and confirmed by magnetic resonance imaging in India (Grover et al., 2003; Fig. 38.8).

Microbiologic confirmation of disease in the neonate should be sought using specimens from multiple sites. For infants and children unable to expectorate sputum, gastric aspirates are considered the specimens of choice. Additional sources for culture include endotracheal aspirate, bronchial washing, middle-ear

• **Fig. 38.8** The sagittal magnetic resonance image on the *left* demonstrates destruction of the T9 to T11 vertebral bodies with the collapse of the T10 vertebral body, leading to a kyphotic deformity causing cord compression. A large prevertebral collection is also seen. The image on the *right* demonstrates destruction with collapse of the L5 and S1 vertebral bodies. (From Grover SB, Pati NK, Mehta R, Mahaian H. Congenital spine tuberculosis: early diagnosis by imaging studies. *Am J Perinatol.* 2003;20:147–152.)

discharge, bone marrow, lymph node tissue, peritoneal fluid, or other suspected sites of disease. CSF should be analyzed and cultured, although isolation of *M. tuberculosis* from CSF is uncommon (Hageman et al., 1980; Abughali et al., 1994). Traditionally the detection of mycobacterial organisms by smear test or culture has been considered difficult because children have paucibacillary disease relative to adults. With three morning gastric aspirates collected appropriately in hospitalized children with a clinical diagnosis of TB, only 40% of children had positive culture results (Starke and Taylor-Watts, 1989). Only 5%–12% of samples are actually acid-fast smear positive (Gomez-Pastrana et al., 2001), though fluorescent staining methods are more sensitive than AFB smear tests (Ryan et al., 2014). In comparison, cultures of aspirates from infants (younger than those in the childhood studies discussed before) evaluated at the same institution had a 75% yield (Starke and Taylor-Watts, 1989; Vallejo et al., 1994).

The improved diagnostic yield in infants likely reflects more widely disseminated and progressive disease, with higher bacillary loads. Hageman et al. (1980) found positive cultures of *M. tuberculosis* in 10 of 12 gastric aspirates, 3 of 3 liver biopsy specimens, 3 of 3 lymph node specimens, and 2 of 4 bone marrow biopsy specimens. Among the 31 cases reviewed by Cantwell et al. (1994), noninvasive procedures and biopsy were useful for the diagnosis of congenital TB in most infants (Table 38.9). More recent reports confirm the high yield of cultures from a variety of specimens in neonates (Mazade et al., 2001; Chou, 2002; Berk and Sylvester, 2004; Premkumar et al., 2008; Wanjari et al., 2008). Histologic examination of tissue may suggest the diagnosis before culture results are available. For example, histopathologic evidence

TABLE 38.9 Results of Diagnostic Procedures Performed on 29 Infants With Congenital Tuberculosis Reported From 1980–1994

| Type of Specimen | Acid-Fast Smear Test ^a | Mycobacterial Culture | Smear Test or Culture |
|------------------------|-----------------------------------|-----------------------|-----------------------|
| Gastric aspirate | 8/9 | 8/9 | 9/11 |
| Endotracheal aspirate | 7/7 | 7/7 | 7/7 |
| Ear discharge | 2/2 | 1/1 | 2/2 |
| Cerebrospinal fluid | 1/2 | 1/2 | 1/2 |
| Urine | 0/2 | 0/2 | 0/2 |
| Peritoneal fluid | 1/1 | 1/1 | 1/1 |
| Bronchoscopic specimen | 1/1 | 1/1 | 1/1 |
| Biopsy specimen | 14/19 | 11/12 | 16/21 |
| Lymph node | 7/8 | 6/6 | 7/8 ^b |
| Liver | 4/6 | 1/2 | 4/6 ^b |
| Skin | 1/3 | 1/1 | 1/3 |
| Lung | 1/1 | 1/1 | 2/2 |
| Bone marrow | — | 1/1 | 1/1 |
| Ear | 1/1 | 1/1 | 1/1 |

^aResults are expressed as the number of positive results per number of patients tested.

^bAll biopsy specimens of lymph nodes and liver that tested negative on the smear test and culture showed histopathologic changes consistent with tuberculosis (i.e., giant cell transformation of granulomas, with or without caseation).

Modified from Cantwell MF, Shehab ZM, Costello AM, et al. Brief report: congenital tuberculosis. *N Engl J Med.* 1994;330:1051–1054.

of granulomas or AFB on stained tissue samples of skin lesions, lymph nodes, and the liver has suggested the diagnosis before culture results were available (Davis et al., 1960; Hageman et al., 1980; Berk and Sylvester, 2004).

Whereas *M. tuberculosis* can require 7–42 days for growth by the standard culture technique, results from techniques such as PCR may be available within 48 hours. A comparison of PCR, AFB smear tests, and culture with clinical diagnosis in children found a sensitivity of 60% and a specificity of 97% (Smith, 2002). Although PCR has been useful for diagnosing congenital TB in a few case reports, it is not sensitive enough to preclude the culture of specimens. Moreover, isolation of *M. tuberculosis* by culture is still important to determine susceptibilities and to optimize treatment.

The mother of a newborn in whom congenital TB is suspected is often asymptomatic or has subclinical disease. In the series of congenitally infected infants reported by Hageman et al. (1980), most of the mothers (16 of 26) did not have a diagnosis until after the disease became apparent in their infants. Cantwell et al. (1994) found that 50% of the mothers of infected infants were not ill at the time their newborns exhibited clinical signs of disease. Evaluation of the mother should include a TST, a chest radiograph, and, if the radiograph is consistent with TB, collection of sputum for microbiologic confirmation. Extrapulmonary disease such as meningitis or peritonitis occurs with some regularity among mothers

with children born with congenital TB (Laartz et al., 2002; Centers for Disease Control and Prevention, 2005), and evaluation may need to be extended to identify such sites if pulmonary disease is not discovered. In mothers with no clinical evidence of disease, endometritis should be considered (Nemir and O'Hare, 1985). Pathologic examination and culture of the placenta (if available) or endometrial biopsy can confirm the diagnosis of genital transmission (Niles, 1982; Cooper et al., 1985; Asensi et al., 1990; Cantwell et al., 1994; Balasubramanian et al., 1999; Surve et al., 2006). In several case reports the diagnosis of maternal TB was ultimately made by endometrial biopsy and culture (Pejham et al., 2002). Culture of amniotic fluid should be performed when genital involvement is suspected. All mothers with TB should be tested for HIV infection, and if the mother is seropositive, the infant should be evaluated for perinatally acquired HIV infection.

Treatment and Management

The successful management of congenital TB depends on early recognition and treatment of disease. In suspected cases, treatment should not be delayed while culture results or results of other diagnostic tests are awaited. Multiple drug therapy for an extended duration has long been recognized as the standard of care for TB. Because of the rarity of the condition, clinical trials have not been conducted to establish the optimal treatment regimen for congenital TB. It is assumed that the regimens used for older infants and children are safe and effective for the treatment of neonates with congenital TB. Consultation with a pediatric infectious disease specialist or TB expert is advised.

Until susceptibility results are known, infants with proven or suspected TB should be treated with a four-drug regimen consisting of INH, rifampin, pyrazinamide, and ethambutol (Table 38.10). Some experts recommend administration of three drugs (INH, rifampin, and pyrazinamide) if antimicrobial resistance is not suspected in the mother (e.g., known susceptible strain in either the mother or the source case or the mother has no risk factors

for resistant *M. tuberculosis*). Supplementation with pyridoxine, although not routinely recommended for otherwise healthy older children, should be provided to breastfeeding infants receiving INH. If the *M. tuberculosis* isolate is determined to be susceptible, the regimen can be narrowed to three drugs (INH, rifampin, and pyrazinamide) for the first 2 months of initial treatment, and subsequently to two drugs (INH and rifampin) to complete the continuation phase of treatment. The adjunctive use of corticosteroids is recommended for the treatment of TB meningitis on the basis of decreased mortality and morbidity demonstrated in adults and children (Girgis et al., 1991) and has been used (though controversial) in cases of endobronchial obstruction, pericardial/pleural disease. Once the infant has discharged to home, directly observed therapy is recommended to ensure adherence and to prevent relapse.

The optimal duration of treatment for infants with congenital TB is unknown. The typical duration of treatment for susceptible *M. tuberculosis* is 6 months for pulmonary disease, pulmonary disease with hilar adenopathy, or hilar adenopathy alone (American Academy of Pediatrics Committee on Infectious Diseases, 2015). With the exception of meningitis, extrapulmonary disease can be treated for the same duration as pulmonary disease. For meningitis, the duration is extended to 9–12 months. The duration of treatment for drug-resistant disease can be prolonged for up to 24 months or longer depending on the clinical course (American Academy of Pediatrics Committee on Infectious Diseases, 2015). Most experts would treat neonates with congenital TB for 9–12 months because of the decreased immunocompetence of neonates (Starke, 1997).

Although there is a substantial amount of data to support the safety of INH, data on the safety and pharmacokinetics of other agents are limited. While INH toxicity is rare in otherwise healthy infants and children, for which monitoring is not required, routine determination of serum transaminase levels and careful monitoring of hepatitis symptoms are indicated in children with severe TB (e.g., miliary or meningitis), those with concurrent liver or biliary

TABLE 38.10

Drugs Commonly Used for Treatment of Tuberculosis in Infants, Children, and Adolescents

| Drug | Dose Forms | Daily Dose (mg/kg) | Twice per Week Dose (mg/kg) | Maximum Dose/ Dosage | Adverse Reactions |
|--------------|--|--------------------|-----------------------------|-------------------------------------|---|
| Ethambutol | Tablets (100 mg, 400 mg) | 20 (15–25) | 50 | 2.5 g | Optic neuritis (usually reversible), decreased red–green color discrimination, gastrointestinal tract disturbances, hypersensitivity |
| Isoniazid | Scored tablets (100 mg, 300 mg) Syrup 10 mg/mL | 10–15 ^a | 20–30 | 300 mg daily, 900 mg twice per week | Mild hepatic enzyme level elevation, hepatitis, ^a peripheral neuritis, hypersensitivity Diarrhea and gastric irritation caused by vehicle in the syrup |
| Pyrazinamide | Scored tablets (500 mg) | 30–40 | 50 | 2 g | Hepatotoxic effects, hyperuricemia, arthralgia, gastrointestinal tract upset |
| Rifampin | Capsules (150 mg, 300 mg) Syrup-formulated capsules | 10–20 | 10–20 | 600 mg | Orange discoloration of secretions or urine, staining of contact lenses, vomiting, hepatitis, influenza-like reaction, thrombocytopenia, pruritus; oral contraceptives may be ineffective |

^aWhen isoniazid in a dosage exceeding 10 mg/kg per day is used in combination with rifampin, the incidence of hepatotoxic effects may be increased.

From American Academy of Pediatrics Committee on Infectious Diseases. Section 3: summaries of infectious diseases, tuberculosis. In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. 2015 Red Book: Report of the Committee on Infectious Diseases. 30th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2015:805–831.

disease, or those receiving other potentially hepatotoxic drugs. Routine monitoring of liver function should also be considered for neonates with congenital TB given the paucity of data on adverse effects of anti-TB agents in this age group (Patel and DeSantis, 2008). The risks of optic neuritis with ethambutol should be considered when this agent is used, and vision should be monitored periodically.

The prognosis for congenital TB was dismal in the prechemotherapy era, the diagnosis often being only made at autopsy. Although the survival rate subsequently increased, mortality remained approximately 50% secondary to delayed diagnosis. In a review of 26 cases reported between 1952 and 1980, 12 patients (46%) died, of which nine were untreated but diagnosed at autopsy. Subsequent reviews demonstrated a decrease in case fatality (see Table 38.8) with earlier diagnosis and treatment. Timely diagnosis and initiation of anti-TB therapy are critical for a favorable outcome.

Prevention

Early diagnosis and treatment of *M. tuberculosis* infection in women of childbearing age are the optimal methods of preventing congenital TB. Risk factors for acquiring *M. tuberculosis* infection or progressing to disease should be assessed at prenatal visits, and women with high risk of *M. tuberculosis* infection should undergo tuberculin skin testing or IGRA as recommended by the CDC (Centers for Disease Control and Prevention, 2000). More recent studies indicate that the performance of IGRA is not altered during pregnancy, with better test completion rates compared with TST (Lighter-Fisher and Surette, 2012; Molina et al., 2016). Studies have shown the greatest discordance with IGRAs and TSTs, especially among those with prior bacille Calmette–Guérin vaccination (reviewed in Mathad and Gupta, 2012). Women who test positive for *M. tuberculosis* infection either by a TST or IGRA should undergo evaluation for active disease. The treatment of active TB during pregnancy is considered standard, and early treatment has been shown to improve maternal and neonatal outcome (Figueroa-Damian and Arredondo-Garcia, 1998). The benefit of treating TB during pregnancy far outweighs the potential risk to the pregnant woman and her fetus. The treatment of latent tuberculosis infection (LTBI) during pregnancy is somewhat more controversial. It is recommended that pregnant women at high risk of active disease such as those with HIV infection or those recently infected should start immediate treatment of LTBI. Although there is no demonstrated teratogenic potential for the use of INH, there is concern that pregnant and postpartum women are more vulnerable to INH-related hepatotoxicity on the basis of retrospective analysis (Franks et al., 1989; Malhamme et al., 2016). Prospective data on the risks of INH-induced hepatotoxicity are currently being acquired in a large clinical trial of HIV-infected pregnant women undergoing treatment of LTBI and will provide more information on the true risks of INH (IMPAACT Trial P1078/ NCT0149038 <http://impactnetwork.org/studies/index.asp#ongoing>). More data are needed on the safety in pregnant women not infected with HIV. For those at less risk, treatment can be deferred until weeks to months after delivery. However, treatment should not be delayed, as some suggest, such that the postpartum period may be associated

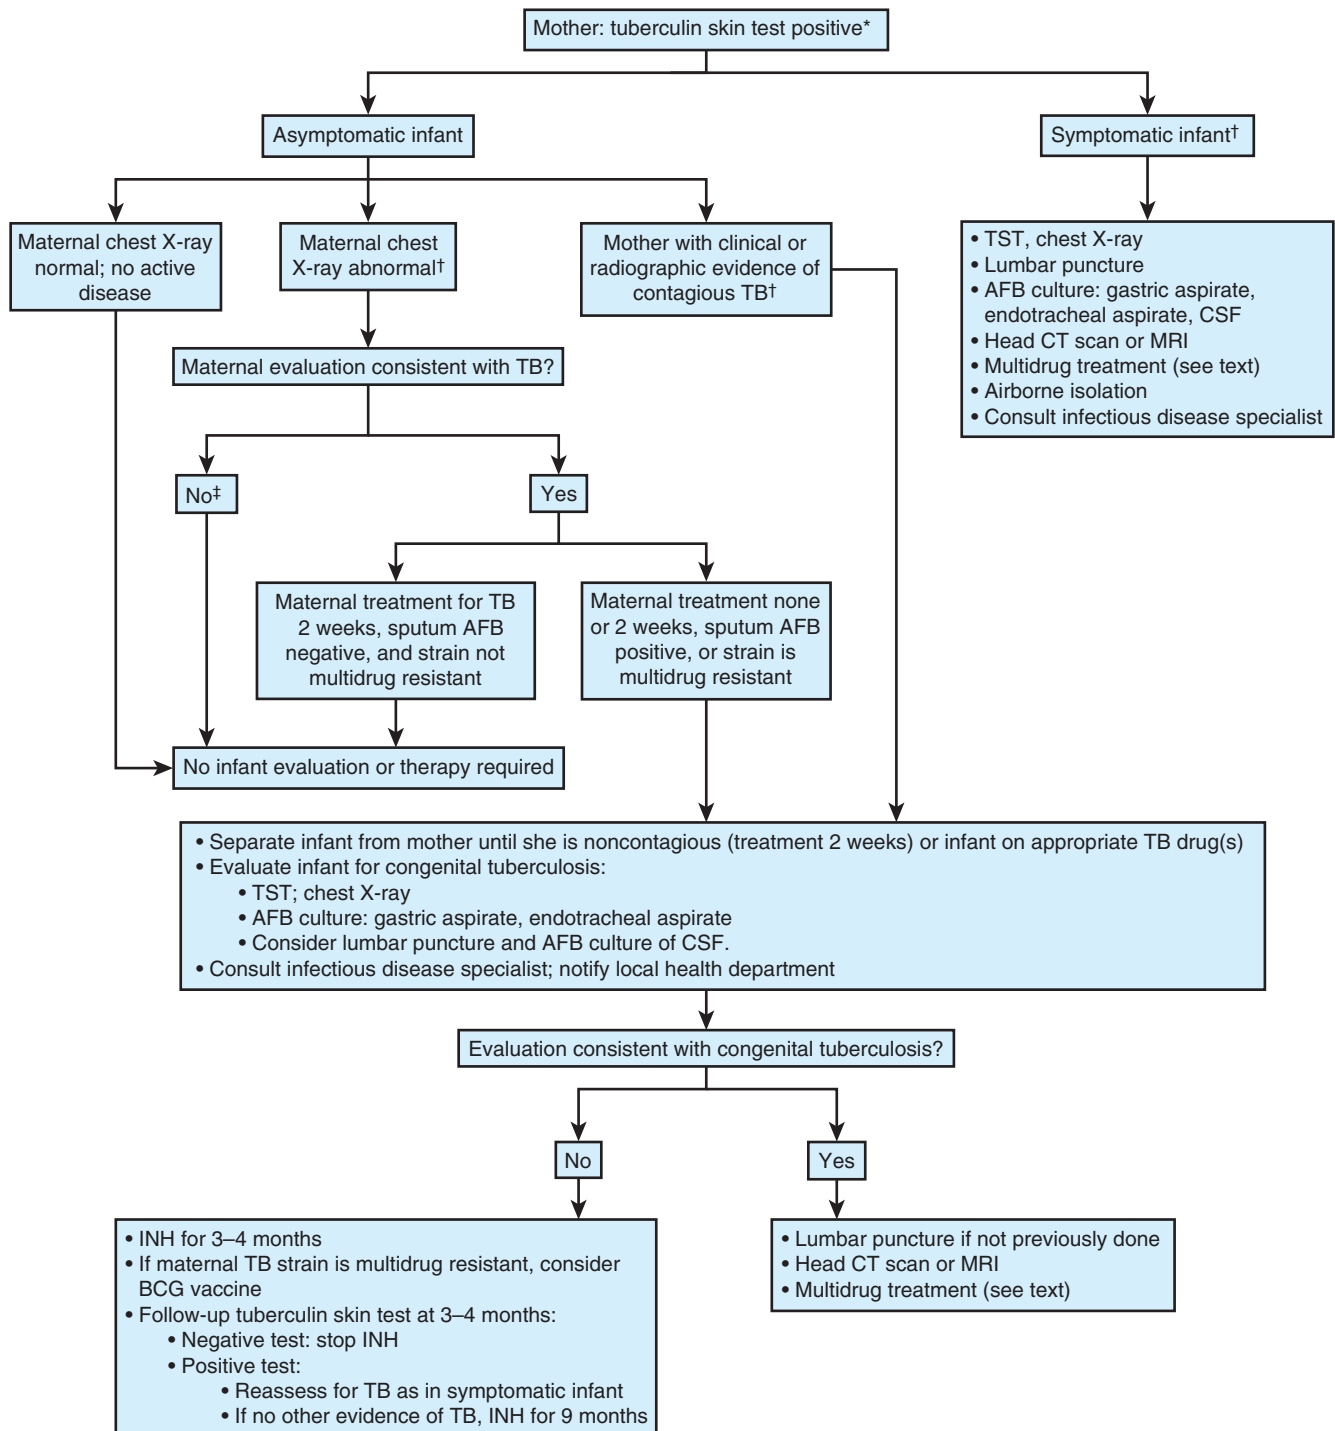

with an increased risk of more severe forms of active disease (Cheng et al., 2003).

The treatment of neonates born to mothers who have LTBI or TB is outlined in Fig. 38.9. Recommendations are based on the categorization of infection in the mother and the potential risk of transmission of TB to the neonate (American Academy of Pediatrics Committee on Infectious Diseases, 2015). Neonates born to mothers with potentially contagious TB should be evaluated for congenital TB. Separation of the neonate and the mother is necessary only in cases in which the mother is highly infectious at the time of delivery, is nonadherent to medication, has drug-resistant disease, or has not been treated for at least 2 weeks (reviewed in Mittal et al., 2014). The mother with latent TB is not contagious. To prevent reactivation disease in the mother and subsequent exposure of the neonate, the mother should receive treatment with INH for latent TB. In addition, latent TB in the mother may be a marker for contagious TB within the household, and it is recommended that all household members and close contacts of the mother be evaluated for TB.

Breastfeeding is not contraindicated in women with LTBI. The breast milk of a woman with TB does not contain tubercle bacilli. For women with TB who are potentially infectious and separated from the newborn, breast milk may be manually expressed and fed to the newborn. Once the mother is noninfectious or the newborn is receiving therapy, breastfeeding can be resumed. The exception, however, is the mother with an active tuberculous breast lesion. In this situation the breast milk may be pumped and discarded until resolution of the lesion (Efferen, 2007).

With regard to isolation practices, airborne precautions are recommended for the following pediatric patients: (1) children and adolescents with adult-type cavitary disease, (2) those with extensive pulmonary involvement, (3) those with laryngeal involvement, (4) those with smears positive for AFB, and (5) congenitally infected neonates undergoing oropharyngeal procedures (e.g., endotracheal intubation) (American Academy of Pediatrics Committee on Infectious Diseases, 2015). In general, children younger than 10 years are not considered contagious given the lack of tussive force they are able to generate and the paucibacillary load. However, the adult contacts of that child may be the source case and potentially contagious. Thus visitation of the hospitalized pediatric patient should be restricted to adults in whom contagious TB has been excluded. Hospitalized children with sputum smears (if obtained) negative for ABS require standard precautions, assuming that contagious TB has been excluded in the visitors.

Compared with older children, neonates likely have a higher concentration of bacilli in their sputum. As noted previously, AFB smear tests on tracheal aspirates and other specimens are frequently positive in this population compared with older children. Transmission of TB from congenitally infected neonates to other hospitalized infants and healthcare workers has been reported and is likely related to aerosolization of bacilli during respiratory manipulation (Lee et al., 1998; Laartz et al., 2002; Crockett et al., 2004; Mouchet et al., 2004). Neonates suspected of having congenital TB should be placed in respiratory isolation if they are intubated or if they are undergoing any procedure with the potential for aerosolization of infected sputum. Exposed infants, visitors, and healthcare workers should undergo evaluation for *M. tuberculosis* infection or disease.

*Acid-fast bacillus culture of amniotic fluid and placenta, if available; placenta for histopathologic examination.

†Mother with chest radiographic findings consistent with old, healed tuberculosis.

• **Fig. 38.9** Management of Infants Born to Mothers With a Positive Tuberculin Skin Test Result. An asterisk indicates that household contacts should have a tuberculin skin test and further evaluation for contagious tuberculosis. The local health department should be consulted. The mother should receive treatment for latent tuberculosis. All persons with tuberculosis should be tested for human immunodeficiency virus infection. AFB, Acid-fast bacilli; BCG, bacille Calmette-Guérin; CSF, cerebrospinal fluid; CT, computed tomography; INH, isoniazid; MRI, magnetic resonance imaging; TB, tuberculosis; TST, tuberculin skin test. (Modified from American Academy of Pediatrics: Tuberculosis. In Pickering LK, ed: 2003 Red Book: Report of the Committee on Infectious Diseases. 26th ed, Elk Grove Village, IL: American Academy of Pediatrics; 2003:642.)

Newborn Sepsis and Meningitis

PATRICIA FERRIERI AND LINDA D. WALLEN

KEY POINTS

- Group B streptococcus and *Escherichia coli* account for most of the cases of neonatal early-onset bacterial sepsis.
- Prevention of infection by maternal treatment is the main factor accounting for the decreased incidence of early-onset group B streptococcus sepsis.
- Microbiologic cultures represent the mainstay for diagnosis of infection.
- Management of the asymptomatic newborn at risk of infection because of maternal risk factors is in transition, with recent evidence supporting evaluation and treatment of a small proportion of asymptomatic infants.
- Ampicillin and gentamicin are recommended as initial therapy in neonates with suspected bacterial sepsis. Treatment can then be narrowed appropriately on the basis of the results of antibiotic susceptibility studies.

Throughout pregnancy the fetus is protected from bacterial and viral infections by the chorioamniotic membranes, the placenta, and various antibacterial factors that are poorly described in amniotic fluid. There are several mechanisms by which bacteria can reach the fetus or newborn and initiate infection. Maternal bloodstream infections, caused by bacteria such as *Listeria monocytogenes* and *Mycobacterium tuberculosis*, can reach the fetus and cause infection. Bacteria such as group B streptococcus (GBS) can be acquired from the vagina, cervix, or fecal contamination of the birth canal through either ruptured or intact membranes, leading to amnionitis, intrauterine pneumonitis, and premature delivery (Ancona et al., 1980; Payne et al., 1988; Ferrieri, 1990; Larsen and Sever, 2008). It is thought that subclinical infections of the fetus, amniotic fluid, membranes, or placenta may contribute to the onset of preterm labor and the delivery of preterm neonates. Finally, infection can occur via aspiration of birth canal contents or colonization of mucosal surfaces during passage through the birth canal, leading to pneumonia, followed by bacteremia and sepsis on day 1 or later; this may be the mode by which *Neisseria gonorrhoeae*, *Escherichia coli*, and GBS are acquired.

Early-onset bacterial sepsis remains a major cause of neonatal morbidity and death, although the sepsis-associated death rates per 100,000 live births declined significantly from 2001–2011. Much of this decline in mortality was because of the introduction of intrapartum antibiotic prophylaxis in pregnant women during

labor and delivery (Schrag et al., 2002; Schrag and Stoll, 2006; Centers for Disease Control and Prevention, 2007, 2009). Mortality rates in infected premature neonates and very immature neonates are significantly higher than in term neonates. Major improvements in neonatal intensive care and early identification and recognition of infected neonates have contributed to reduced mortality rates in the newborn period.

Pathogenesis of Early-Onset Neonatal Bacterial Infections

There are multiple portals through which bacteria can enter and infect the newborn. The primary portals of entry appear to be the respiratory tract, as suggested by the high frequency of acute respiratory distress and pneumonia, which occurs in newborns with early-onset disease. Acquisition via the placenta is suggested in some instances by the presentation of high-grade bacteremia and severe sepsis clinically apparent at the time of birth in the presence of intact membranes in neonates born by cesarean delivery. The primary maternal event in this sequence, leading to infection of the fetus and newborn, is colonization of the maternal genital tract with organisms such as GBS. Bacteria that reside in the cervix, vagina, or rectum can ascend into the amniotic cavity through intact or ruptured membranes and lead to chorioamnionitis. Bacteria can initially spread into the choriodecidual space and can occasionally cross intact chorioamniotic membranes. Although organisms recovered from the amniotic sac in the mother are usually polymicrobial and include organisms such as GBS, group D enterococcus, aerobic gram-negative bacteria, and anaerobes such as *Bacteroides* spp. (Gibbs et al., 1980), a single organism causing bacterial sepsis is the rule in de novo sepsis of the newborn. Genital microplasmas are at times recovered from women as well as *Chlamydia* spp., but their precise pathogenic role is unclear (Pankuch et al., 1984; Krohn et al., 1995). *Ureaplasma* spp. and *Chlamydia* spp. can be isolated from neonates' respiratory tract after birth; these plus *Mycoplasma hominis* can be recovered from the respiratory tract after birth, but they are not associated with sepsis syndrome.

Although many microorganisms recovered from the amniotic cavity are thought to induce spontaneous preterm labor, and possibly premature rupture of membranes, the exact mechanisms by which this may occur are debatable. Clinical or subclinical chorioamnionitis

can incite a marked inflammatory response with the release of cytokines that can contribute to the onset of preterm labor and premature rupture of membranes. Other risk factors for clinical intra-amniotic infection include young maternal age, prolonged labor, prolonged rupture of membranes (≥ 18 hours), internal scalp fetal monitoring, the presence of urinary tract infections, and a history of bacterial vaginosis (Newton et al., 1989; Soper et al., 1989). Despite inherent antibacterial properties in amniotic fluid, these may not be sufficient to overcome a large bacterial inoculum, because of rapid multiplication of bacteria during a prolonged labor or the absence of type-specific maternal antibodies for various pathogens (Ferrieri, 1990).

Newborns who immediately display signs of respiratory distress and after birth undoubtedly have onset of infection before or during labor and delivery. With hypoxia and acidosis in utero, the newborn may gasp and inhale contaminated amniotic fluid, leading to pneumonia, bloodstream infection, sepsis, and a severe systemic response syndrome. Newborns who display such signs at birth or within a short time after birth and very low birth weight (VLBW) newborns have the highest mortality rates. Newborns who have an initial asymptomatic period after birth may display symptoms gradually as the organisms multiply in the lungs and in the blood. An example of another invasive site of entry is the scalp lesion created by a monitoring device, which becomes contaminated in the setting of amniotic fluid infected with GBS. An overarching mechanism for continued bacteremia is the absence of sufficient local and systemic host defenses, such as adequate complement levels or type-specific immunity against the invading microorganism (Ferrieri, 1990).

The inflammatory cascade is initiated by activation of macrophages by bacterial cell wall constituents, toxins, or enzymes. A number of proinflammatory cytokines can be released, such as interleukin (IL)-6, IL-8, and tumor necrosis factor- α (TNF- α). These cytokines can alter vascular permeability and vascular tone, decrease myocardial contractility, activate clotting systems, increase pulmonary vascular resistance, and activate other phagocytic cells, such as polymorphonucleocytes (PMNs). Ideally, proinflammatory and antiinflammatory cytokines would be balanced; however, this is usually not the case, and the bacteria persist, with subsequent consequences. It is common in newborns, and particularly in preterm neonates, to have dissemination of bacteria to other organs such as the meninges, kidneys, and bone.

Epidemiology of Early-Onset Bacterial Infections

Before the availability and use of antibiotics in the late 1940s and 1950s, there were few survivors of neonatal bacterial sepsis, contributing to the high perinatal mortality rate of that period. There have been changes in the types of bacteria responsible for neonatal infection over the years. In the 1930s and 1940s, group A streptococcus was a prominent cause of neonatal sepsis; this organism is now rather rare (Bizzarro et al., 2005). In the 1950s, nursery outbreaks of *Staphylococcus aureus* infections appeared across North America and Europe, prompting changes in techniques of hygiene and encouraging the development and use of penicillinase-resistant antibiotics (Bizzarro et al., 2005). In the 1960s, *E. coli* became the most common cause of bacterial sepsis, followed in the 1970s by GBS. Even in an era of intrapartum antibiotic prophylaxis of GBS-colonized mothers, GBS remains the most common bacterial pathogen in neonatal centers of North America and Europe, followed by *E. coli* (Schrag et al., 2006). An update on neonatal sepsis at

Yale, between 1989 and 2003, revealed an overall decrease in the rate of sepsis caused by both GBS and *E. coli* (Bizzarro et al., 2005). Regional differences exist, however, and must be considered before an attempt is made to apply epidemiologic data to individual perinatal units. For example, *L. monocytogenes* is a frequent isolate in some western European countries, and *S. aureus* is found commonly in Germany and Scandinavia (Posfay-Barbe and Wald, 2009).

The incidence of early-onset bacterial infection is variable and ranges from 1–5 per 1000 live births; however, it is clear that the incidence has declined as a result of intrapartum antibiotic therapy (Centers for Disease Control and Prevention, 2007, 2009). Data from the Centers for Disease Control and Prevention (CDC) revealed a downward trend from 2000–2003 (from 0.52–0.31 case per 1000 live births), followed by an increase from 2003–2006 (from 0.31–0.40 case per 1000 live births) (Centers for Disease Control and Prevention, 2009). Stratified by race, the incidence increased significantly among black infants from 2003–2006 (from 0.53–0.86 case per 1000 live births), whereas the incidence among white infants did not change significantly (from 0.26–0.29 case per 1000 live births). When stratified by gestational age, the average incidence of early-onset GBS disease among preterm infants during 2003–2006 was 2.8-fold higher among black infants than among white infants (1.79 cases versus 0.67 case per 1000 live births). In both preterm black and preterm white infants there were increases in the incidence of early-onset disease from 2003–2006 that were not statistically significant. Early-onset disease among term white infants was stable from 2003–2006, whereas in term black infants there was a significant increase in the incidence during this period, from 0.33–0.7 case per 1000 live births.

The overall rates of late-onset GBS disease remained stable from 2000–2006 (0.36 case versus 0.30 case per 1000 live births) (Centers for Disease Control and Prevention, 2009). When stratified by race, late-onset disease incidence among black infants decreased significantly by 42% from 2005–2006 (0.95 case versus 0.55 case per 1000 live births). Between 2003 and 2006 there were no significant trends among black or white infants.

Infants described with early-onset sepsis frequently have one or more identifiable risk factors (Dutta et al., 2010; Puopolo et al., 2011). Prematurity is considered the single greatest risk factor for early-onset bacterial infections. Because it is accepted that extremely low birth weight infants have impairment of host defenses, and since preterm birth may be associated with low-grade chorioamnionitis, it is not surprising that the attack rates for infection by pathogens such as GBS are 26–30-fold higher in preterm infants than in term newborns, with an associated high mortality. Other risk factors for early-onset sepsis are maternal age, health and nutrition, colonization with well-known pathogens (e.g., GBS), maternal fever, and longer duration of rupture of membranes (Schuchat et al., 2000; Puopolo et al., 2011). Neonatal susceptibility to GBS infection is increased with deficiencies in circulating levels of GBS type-specific antibody and complement, which is further heightened by any element of neutrophil dysfunction, as may be seen in the more premature infants (Ferrieri, 1990; Foxman, 2007; Nandyal, 2008; Makhoul et al., 2009).

Bacterial Pathogens in Early-Onset Infections

Group B Streptococcal Infections

Since the early 1930s when Rebecca Lancefield reported her grouping system for hemolytic streptococci, group A streptococcus

(*Streptococcus pyogenes*) was widely acknowledged as the major pathogen associated with puerperal sepsis. GBS was initially thought to be a commensal until 1938, when Frye reported seven cases of GBS-associated puerperal fever with three deaths (Eickhoff et al., 1964). Before the 1960s, GBS was not recognized frequently as a cause of human disease. However, in the late 1960s GBS emerged as the leading cause of neonatal sepsis in newborns (Zaleznik et al., 2000; Bizzarro et al., 2005). Before the era of maternal intrapartum prophylaxis, GBS had a reported national incidence of approximately 2 per 1000 live births and was associated with approximately 50% mortality in newborns. As mentioned previously, in the past decade with the introduction of antibiotic maternal prophylaxis there has been a significant decrease in the incidence of GBS to its current rate of approximately 0.32 per 1000 live births for early-onset disease.

Transmission of Group B *Streptococcus* From Mothers to Infants

In the United States, approximately 20%–35% of pregnant women are asymptomatic carriers of GBS in the genital tract and gastrointestinal tract during pregnancy and at the time of delivery (Ferrieri, 1990; Zaleznik et al., 2000; Ferrieri et al., 2004b). The prevalence of GBS colonization during pregnancy differs. Among women who were positive for GBS between 26 and 28 weeks' gestation, only 65% remain colonized at term, whereas 8% of those with negative prenatal culture results were positive for GBS at term (Ancona et al., 1980; Zaleznik et al., 2000). Treatment of GBS-colonized women during pregnancy only temporarily eradicates the organism, and most women are recolonized within several weeks. At birth, 50%–65% of neonates who were born to GBS-colonized mothers have positive GBS cultures from mucous membranes and skin (external ear canal, throat, umbilicus, and anal or rectal sites) (Shet and Ferrieri, 2004). Before the introduction of intrapartum antibiotic prophylaxis, approximately 1%–2% of colonized neonates developed GBS infection, and the overall incidence of neonatal GBS infection was approximately 2 per 1000 live births in the United States. With intrapartum prophylaxis, approximately 60%–80% of GBS cases occur in infants born to women with a negative prenatal GBS screening result (Centers for Disease Control and Prevention, 2010). A small number of GBS-infected infants acquired their bacteremia because of hematogenous transmission through the placenta. In these situations the mother commonly displays signs and symptoms of chorioamnionitis, although it may occur in the absence of maternal symptoms (Baker and Edwards, 1995).

Detection of GBS colonization has been emphasized since approximately 1996; studies to determine the optimal sites of sampling have been key to the effectiveness of intrapartum prophylaxis. GBS resides in the genitourinary and gastrointestinal tracts, where large numbers of gram-negative bacteria are also present. Most colonization studies have revealed high rates of both rectal and vaginal colonization with GBS (Ancona et al., 1980; Hickman et al., 1999; Zaleznik et al., 2000). The use of the selective broth enrichment medium that inhibits the growth of gram-negative enteric bacilli and other normal flora can increase culture sensitivity for GBS to greater than 90%. The most widely used selective medium is Todd–Hewitt broth with either gentamicin or colistin and nalidixic acid. As recommended in a 2010 publication from the CDC, the optimal time for performing prenatal cultures is between 35 and 37 weeks' gestation, and the highest culture yield is obtained when both the lower vaginal area and anal or rectal sites are sampled (Schrag et al., 2002; Centers for Disease Control and Prevention, 2010).

Epidemiologic studies of GBS-colonized women have shown that those with heavy colonization (3+ to 4+) are more likely to transmit GBS to their infants (Ancona et al., 1980). The colonization of GBS in pregnant women may be long-standing, intermittent, or transient. There is a definite association between GBS colonization and other risk factors for neonatal sepsis; these include preterm labor, preterm delivery, premature rupture of membranes, prolonged rupture of membranes, and maternal fever.

In the past few years, rapid diagnostic tests to detect GBS colonization in pregnant women have included real-time polymerase chain reaction (PCR); compared with broth enrichment cultures, there is an approximately 10%–15% increased sensitivity (P. Ferrieri, unpublished data). The advantages of PCR detection of maternal vaginal or rectal colonization are the rapid turnaround time and the increased sensitivity. Although it is more expensive than traditional culture-based detection assays, the results are available 1–2 days sooner. The argument that this does not provide semiquantitative data on the degree of GBS colonization in the mother is moot, because even low-grade colonization in pregnant women is a risk factor for neonatal GBS sepsis. However, women with heavy (3+ to 4+) colonization, determined by semiquantitative assessment of vaginal or rectal cultures, are more likely to pass the microorganism to their infants (Ancona et al., 1980).

Chemoprophylaxis and Intrapartum Antibiotic Therapy

Prevention is of key importance in decreasing the incidence of invasive GBS disease. The challenge has been to widely promulgate screening cultures in pregnant women. Revised guidelines from the CDC were published in 2002 and presented only the culture screening–based approach for prevention and chemoprophylaxis rather than the two preventive approaches published in 1996: a culture screening–based and a risk-based approach (Schrag et al., 2002). The risk-based approach involved the use of antibiotics solely on the basis of the presence of prenatal or intrapartum risk factors such as maternal fever, preterm labor, or premature rupture of membranes (<37 weeks' gestation); prolonged rupture of membranes (≥18 hours); history of a newborn with GBS disease; and GBS bacteruria during pregnancy. Challenges to the implementation of the CDC guidelines, such as failure to seek prenatal care and the use of suboptimal laboratory culture techniques, continue in certain populations. Data for the United States as a whole show a decrease in the incidence of early-onset GBS disease concurrent with the implementation of maternal GBS screen and intrapartum antibiotic prophylaxis guidelines. The current estimate for the overall US population for early-onset GBS disease is 0.32 per 1000 live births (Van Dyke et al., 2009).

Intrapartum Antibiotic Prophylaxis

GBS is sensitive to penicillin, which is the drug of choice because of its narrow spectrum; the alternative is ampicillin. If a mother is allergic to penicillin but not at high risk of anaphylaxis, the use of cefazolin is recommended (Centers for Disease Control and Prevention, 2010). When patients are at high risk of anaphylaxis, tests for antimicrobial susceptibility of prenatal GBS to clindamycin and erythromycin should be performed. If the prenatal GBS is sensitive to clindamycin and erythromycin, patients can receive either of these drugs intravenously (IV) until delivery. When GBS is resistant to clindamycin or erythromycin or the antibiotic susceptibility is unknown, IV vancomycin given every 12 hours until delivery is the current recommendation (Centers for Disease Control and Prevention, 2010). In the United States, GBS exhibits considerable resistance to erythromycin (5%–32%) and clindamycin

TABLE 39.1 Manifestations of Early-Onset and Late-Onset Group B Streptococcal Disease

| Characteristic | Early-Onset Disease | Late-Onset Disease |
|--|------------------------------------|------------------------------------|
| Age at onset | Birth through day 6 of life | Day 7 to 3 months |
| Symptoms | Respiratory distress, apnea | Irritability, fever, poor feeding |
| Findings | Pneumonia, sepsis | Sepsis, meningitis, osteoarthritis |
| Maternal obstetric complications | Frequent | Uncommon |
| Mode of transmission | Vertical, in utero, or intrapartum | Nosocomial, horizontal |
| Predominant serotypes | Ia, III, V ^a | III, Ia, V ^a |
| Effect of intrapartum antibiotic prophylaxis recommended by the Centers for Disease Control and Prevention | Reduces incidence by 85%–90% | No effect |

^aIn decreasing order of frequency.

(3%–21%) (Castor et al., 2008). It is therefore important for antibiotic testing to be done on the group B streptococcal isolates from pregnant women. For laboratories performing PCR on maternal vaginal or rectal cultures, it is recommended that the swabs be placed in a selective enrichment broth containing inhibitory antibiotics (either colistin and nalidixic acid or gentamicin and nalidixic acid) against gram-negative bacteria. If the PCR result is positive, the broth culture can be subcultured, and antibiotic testing can be pursued. Because of the higher sensitivity of PCR compared with the selective broth enrichment culture, the organism will not grow on 10%–15% of occasions.

Group B Streptococcal Sepsis in Neonates

Most infections in newborns occur within the first week of life and are designated as *early-onset disease* (Table 39.1; Centers for Disease Control and Prevention, 2010). In the intensive care unit setting, a common definition of early-onset sepsis is onset of sepsis within 72 hours of birth. Late-onset infections occur in newborns 7 days or older, with most of these infections appearing in the first 3 months of life. Although chemoprophylaxis has led to a significant decrease in the incidence of early-onset GBS disease, there is no evidence that chemoprophylaxis prevents late-onset disease (Hamada et al., 2008; Jordan et al., 2008; Cohen-Wolkowicz et al., 2009). Young infants with early-onset invasive GBS disease usually have pneumonia, sepsis, and less often meningitis, osteomyelitis, or septic arthritis (Koenig and Keenan, 2009). The frequency of meningitis, osteomyelitis, or septic arthritis is higher among infants with late-onset disease.

There are nine antigenically distinct GBS serotypes, based on their capsular polysaccharide analysis (types Ia, Ib, and II–VIII) and a proposed new type, IX (Henrichsen et al., 1984; Slotved et al., 2007; Diedrick et al., 2010). In the United States and western Europe, types Ia, II, and III account for most of the isolates from infants with early-onset disease (Zaleznik et al., 2000; Diedrick

et al., 2010). However, recent studies in the United States have demonstrated that serotypes Ia, III, and V, the latter emerging in recent years (Elliott et al., 1998; Harrison et al., 1998; Diedrick et al., 2010), account for most cases (70%–75%) of early-onset invasive GBS disease in newborns and parturient women (Zaleznik et al., 2000; Diedrick et al., 2010). Late-onset GBS disease in infants is dominated by serotype III, followed by serotypes Ia and V (Shet and Ferrieri, 2004). A polysaccharide capsule is considered the most important virulence factor (Kasper et al., 1996; Paoletti et al., 1997, 2001; Cieslewicz et al., 2005); however, the role of surface-localized GBS proteins (Johnson and Ferrieri, 1984; Ferrieri et al., 2004a; Smith et al., 2004; Lindahl et al., 2005) in pathogenesis and immune protection has gained favor (Maione et al., 2005; Tettelin et al., 2005).

The remaining GBS isolates from invasive disease consist primarily of types Ib and II, but types IV, VI, VII, and VIII compose a small fraction. Type IV GBS represented between 0.4% and 0.6% of colonizing GBS isolates (Diedrick et al., 2010), but it was relatively uncommon for type IV isolates to be found in invasive GBS (Puopolo and Madoff, 2007; Ferrieri et al., 2008). Recent studies in the United Arab Emirates, Turkey, and Zimbabwe showed large proportions of type IV GBS among their isolates (Amin et al., 2002; Moyo et al., 2002; Ekin and Gurturk, 2006; Diedrick et al., 2010). In Zimbabwe it was the fourth most common serotype, accounting for 4.6% of the colonizing and invasive isolates (Moyo et al., 2002). Serotypes VII and VIII are uncommon in Western countries.

Infected infants have low levels of type-specific antibody to the infecting GBS serotype (Baker and Edwards, 2003). Vaccines against the common GBS serotypes have been shown to elicit a specific antibody response in humans (Kasper et al., 1996; Paoletti et al., 1997, 2001; Baker and Edwards, 2003). Sera from these vaccinated humans protected neonatal mice against GBS challenge, suggesting that high-titer GBS immunoglobulin may have the potential to prevent or modulate invasive neonatal GBS disease in infants (Paoletti et al., 1997). The prospect of a multivalent GBS vaccine, with or without conjugated GBS surface-localized proteins, makes the study of the common GBS serotypes important because of the possibility of serotype replacement or capsular switch (Lipsitch, 1999; Cieslewicz et al., 2005; Maione et al., 2005; Tettelin et al., 2005).

Escherichia Coli Infections

Historically, *E. coli* has been the second most common pathogen causing sepsis and meningitis in newborns. The antigenic structure of *E. coli* is complex and is composed of approximately 150 somatic or cell wall O antigens, 50 flagellar H antigens, and approximately 80 capsular K antigens. However, a limited number of K antigen *E. coli* strains cause meningitis, and approximately 80% of the strains causing meningitis and 40% of the strains causing bacteremia or sepsis express K1 (Mulder et al., 1984). The capsular K1 polysaccharide antigen is highly homologous to the capsular antigen of group B *Neisseria meningitidis*. Because a high percentage of women may have bacteriuria with strains of *E. coli* that express the K1 antigen or are colonized with it at the time of delivery, it is surprising that *E. coli* sepsis or meningitis is not more common. It has been estimated that disease occurs in 1 in 100–200 infants colonized by K1 *E. coli*. Surveillance data from the National Institute of Child Health and Human Development Neonatal Research Network, a consortium of 16 US academic neonatal centers, revealed that in the era of widespread implementation of antibiotic prophylaxis, the rate of *E. coli* sepsis increased from 3.2–6.8 cases per 1000 live births. This increase was observed in the 1998–2000 era

and persisted from 2002–2003. Approximately 85% of *E. coli* infections in VLBW infants were ampicillin resistant (Stoll et al., 2002). However, most evidence suggests that intrapartum antibiotic prophylaxis has not been associated with a concomitant adverse impact of increasing the incidence of *E. coli* or other non-GBS bacterial causes. Among preterm infants, however, the incidence of *E. coli* and ampicillin-resistant *E. coli* infections increased significantly (Bizzarro et al., 2005). A retrospective case–control study performed between 1997 and 2001 concluded that exposure to intrapartum antibiotic prophylaxis in mothers did not increase the odds of invasive, early-onset *E. coli* infection. In fact, among term infants, exposure to 4 hours or more of intrapartum antibiotic therapy was associated with decreased odds of early-onset *E. coli* infection (Schrag et al., 2006).

Listeria Monocytogenes Infections

L. monocytogenes is a small, facultative anaerobic, gram-positive motile bacillus that produces a narrow zone of beta hemolysis on blood agar plates and can be confused with GBS unless a careful Gram stain, a catalase reaction, and other tests are performed. Most disease is due to three primary serotypes: 1a, 1b, and 4b. The last serotype has been described in most outbreaks of listeriosis (Posfay-Barbe and Wald, 2009). Most cases of listeriosis appear to be food-borne, including those acquired by pregnant women.

Foods that can be contaminated by *L. monocytogenes* include raw vegetables such as cabbage, raw milk, fish, poultry, processed chicken, beef, and hot dogs (Schlech, 2000). Transmission to the fetus occurs through either a hematogenous (transplacental) route or via an ascending infection through the birth canal. Frequently, infections with *Listeria* spp. early in gestation result in abortion; later in pregnancy, infection with *Listeria* spp. can result in premature delivery of a stillborn or infected newborn. Approximately 70% of *Listeria*-infected women deliver before 35 weeks' gestation. Illness in the mother may be undetected because of vague influenza-like illnesses that may not come to medical attention. In approximately half of perinatal cases, illness in the mother has preceded delivery by 2 days to 2 weeks. At autopsy of stillborn neonates or of those who die in the perinatal period, granulomas may be found throughout organs such as the liver and lungs, and infection is widely disseminated, including involvement of the meninges. Treatment of *Listeria* spp. infection or bacteremia during pregnancy can prevent infection in the fetus (Kalstone, 1991). Like GBS infection, *Listeria* spp. infection may have either an early-onset or a late-onset presentation. Epidemics of neonatal *Listeria* spp. infection have been described after ingestion of contaminated foods such as cheese or coleslaw. The first clearly documented food-borne (coleslaw) outbreak of listeriosis was in 1981 from the Maritimes in Canada (Schlech, 2000); it was associated with a fatality rate of 27%. There are reports of repeated abortions in women with colonization in the gastrointestinal tract, and cold-enrichment cultures can be performed to try to detect fecal carriage in such women. However, cold enrichment cultures are inferior to selective media for *Listeria* spp. in isolating the organism from various foods or stool specimens. Rapid antigen tests based on nucleic acid amplification are not in common use in clinical diagnostic laboratories. There is no current vaccine for *Listeria* spp. infection, but preventive measures have included the surveillance programs from the US Department of Agriculture, prohibiting the sale of contaminated meats. Between 1996 and 2006, the incidence of *Listeria* spp. infections declined by 36%; however, an outbreak of disease in 2002 related to contaminated

turkey meat led to 54 illnesses, 8 deaths, and 3 fetal deaths in 9 states (Posfay-Barbe and Wald, 2009).

Miscellaneous Bacterial Pathogens

The bacteria responsible for early-onset neonatal sepsis have changed dramatically over time. There are regional differences in the organisms commonly responsible for early-onset sepsis. In addition to the organisms mentioned previously, other bacterial pathogens associated with early-onset bacteremia or sepsis in newborns include *Enterococcus* spp., viridans group *Streptococcus* spp., *Klebsiella* spp., *Enterobacter* spp., *Haemophilus influenzae* (typeable and nontypeable), *S. aureus*, *Streptococcus pneumoniae*, group A streptococcus and other beta-hemolytic streptococci, and coagulase-negative staphylococci.

Clinical Signs of Bacterial Sepsis

There is great variability in the clinical presentations of neonates with early-onset bacterial sepsis (Box 39.1). Most neonates exhibit respiratory distress in the first 12 hours of life, frequently immediately after birth. In these neonates the progression may be rapid, with cardiovascular instability, shock, and death. Presentation within the first 12 hours of life suggests that the infection with pneumonia and bacteremia occurred at or near the time of birth or during the immediate postnatal period. Neonates with hypoxia in utero may gasp, inhaling contaminated amniotic fluid and setting the stage for early-onset pneumonia, bacteremia, and sepsis.

The signs of early-onset infection may be subtle, with tachypnea suggesting “wet lung disease,” or may be more overt, with respiratory distress and hypotension. Because the signs of sepsis can be relatively nonspecific, such as poor feeding and increased sleepiness, they can be overlooked. In newborn, intermediate care, or intensive care nurseries, one must be attuned to subtle abnormal findings in newborns. The clinical signs of neonatal sepsis include hyperthermia or hypothermia, respiratory distress, apnea, cyanosis, jaundice, hepatomegaly, abdominal distention, feeding abnormalities, and neurologic abnormalities. Autopsy findings in preterm infants with fatal early-onset GBS infection suggested that surfactant-deficiency respiratory distress syndrome was common (Payne et al., 1988).

Laboratory Testing

Many laboratory tests have been evaluated for infants with possible sepsis, and the results must be interpreted with caution, assessing

• BOX 39.1 Common Clinical Signs of Neonatal Sepsis

- Abnormal neurologic status: irritability, lethargy, poor feeding
- Abnormal temperature: hyperthermia or hypothermia
- Apnea
- Bleeding problems: petechiae, purpura, oozing
- Cardiovascular compromise: tachycardia, hypotension, poor perfusion
- Cyanosis
- Gastrointestinal symptoms: abdominal distention, emesis, diarrhea
- Jaundice
- Respiratory distress: tachypnea, increased work of breathing, hypoxemia
- Seizures

| | | Bacterial Infection Present | | |
|------------------------|----------|-----------------------------|----------------------------|--|
| | | YES | NO | |
| Laboratory Test Result | POSITIVE | True Positive TP | False Positive FP | Positive Predictive Value = (TP)/(TP+FP) |
| | NEGATIVE | False Negative FN | True Negative TN | Negative Predictive Value = (TN)/(FN+TN) |
| | | Sensitivity = (TP)/(TP+FN) | Specificity = (TN)/(FP+TN) | |

• **Fig. 39.1** The relationships among sensitivity, specificity, positive predictive value, and negative predictive value in bacterial infections. *FN*, Number of infants with infection with an incorrect diagnosis by the test of being healthy; *FP*, number of healthy infants with an incorrect diagnosis by the test of being infected; *TN*, number of healthy infants with a correct diagnosis by the test of not being infected; *TP*, number of infants with infection correctly diagnosed by the test.

the sensitivity and specificity of a particular test as well its positive and negative predictive accuracy (Fig. 39.1). The sensitivity of a test is defined as the proportion of individuals with proven or probable sepsis in whom the result is abnormal; the specificity is the proportion of healthy or uninfected infants in whom the result is normal. Ideally, a test would have a high sensitivity and a high specificity, but this is rarely achievable. High sensitivity is the most desirable characteristic when dealing with serious and treatable diseases such as neonatal sepsis. Because sepsis is generally treated with antibiotic agents that have a low toxicity, diagnostic tests do not need to have a high specificity but should have a high sensitivity, which will allow sepsis to be excluded. A positive predictive accuracy is the probability that an infant with an abnormal laboratory result is infected; a negative predictive value is the probability that infection with a normal or negative result is free of infection. The more sensitive the test, the greater its negative predictive value; the more specific a test, the greater its positive predictive value.

Microbiologic Cultures

Previously, cultures of superficial body sites in newborns (external auditory canal, gastric aspirate, umbilicus, and nasopharynx) were used to identify bacterial pathogens when more specific blood culture results were negative. Surface cultures are no longer used to make clinical decisions, because they are of limited value in predicting the cause of bacterial sepsis in newborns (Evans et al., 1988; Shenoy et al., 2000). Examination of gastric aspirates by Gram stain as a screening mechanism has also lost favor, as has examination for PMNs as a representation of amnionitis because PMNs in the gastric acid have no specificity in predicting bacterial sepsis for the infants (Vasan et al., 1977).

Blood Cultures

The gold standard for detection of bacteremia in newborns with suspected sepsis is a positive blood culture result. With the introduction of newer blood culture detection instruments that are semiautomated and determine the presence of growth from bacterial CO₂ production that is detected by the internal computer of the instrument every minute, the sensitivity of detecting positive blood culture results has increased. Another variable that influences the sensitivity of detection of bacteremia is the volume of blood obtained and placed in the culture bottles. Ideally 1–3 mL of blood from infants should be obtained, but this is not always possible in very small infants.

Most positive blood culture results are detected within 24–48 hours with use of the new technology (Garcia-Prats et al., 2000; Jardine et al., 2006). However, the use of intrapartum antibiotic prophylaxis in mothers with either GBS colonization or suspected amnionitis originating from any cause can reduce the ability to detect bacteremia in newborns. In a term infant who remains asymptomatic at the initiation of antibiotic therapy, stopping antibiotic administration is recommended if the blood culture results remain negative after 48 hours (Polin et al., 2014). However, the decision to discontinue treatment with antibiotics should include the assessment of the infant's clinical condition and should not rely solely on a negative blood culture result. When the suspicion of sepsis is high, clinicians should consider continuing antibiotic therapy for a complete course despite negative blood culture results (Ottolini et al., 2003).

Urine Cultures

The frequency of positive urine culture results in infants with early-onset sepsis is relatively low, and it is rare to find bacteriuria in infants with negative blood culture results (DiGeronimo, 1992). Infants with late-onset sepsis tend to have a higher rate of positive urine culture results (Visser and Hall, 1979). In the era of widespread intrapartum antibiotic prophylaxis in the mother, positive urine culture results may be obscured because of excretion of antibiotics in the urine of newborns. When pyelonephritis is found in newborns, it likely represents metastatic seeding of the kidney during a bout of bacteremia. In the first 72 hours of life, because the yield from urine cultures is low, it is not generally recommended to obtain urine specimens. However, in the newborn older than 72 hours, a urine sample collected by an aseptic technique (urinary catheter or suprapubic bladder aspiration) is an essential part of the sepsis work-up.

Cerebrospinal Fluid

Lumbar punctures are deferred in infants with any instability or uncorrected bleeding disorders. The details of examination of cerebrospinal fluid (CSF) and the diagnostic approach for examining CSF will be discussed in the subsection on Diagnosis in the Neonatal Bacterial Meningitis section.

White Blood Cell Count and Neutrophil Indices

Normal white blood cell (WBC) counts range from 9000–32,000 cells per microliter at the time of birth, and differences in the site

of sampling can affect these values. The absolute neutrophil count (ANC), the absolute band count of immature neutrophils, and the ratio of immature neutrophils to total neutrophils (I/T) are regarded as more useful than total leukocyte counts in the diagnosis of neonatal sepsis.

The lower limit of total neutrophil count rises to 7200 cells per microliter by 12 hours of age, and then declines to approximately 1720 cells per microliter by 72 hours of age (Manroe et al., 1979; Schmutz et al., 2008). Postnatally, the absolute band count also undergoes similar changes, with peak values of 1400 cells per microliter at 12 hours of age, and then declines. In contrast, the I/T ratio is maximum at birth and then declines to 0.12 beyond 72 hours of age (Manroe et al., 1979; Schelonka et al., 1994). The optimal time to obtain WBC counts is after 4 hours of age, and most recommendations are to obtain the first counts at 6–12 hours of age (Centers for Disease Control and Prevention, 2010; Newman et al., 2010). In VLBW infants there is a greater reference range for the total neutrophil counts (Manroe et al., 1979; Mouzinho et al., 1994; Christensen et al., 2009). There are no significant differences in the I/T ratio or absolute immature neutrophil counts in VLBW infants. There is considerable overlap of the cutoff values of the ANC, absolute band count, and I/T ratio between healthy and infected newborns.

There are a number of clinical conditions that affect the total neutrophil count. Prolonged crying, meconium aspiration syndrome, maternal fever, and asphyxia are all associated with an increase in the total neutrophil count, and there may be an increase in the total immature neutrophil forms, as well as an increased I/T ratio. Maternal hypertension is associated with a decrease in the total neutrophil count. At high altitudes, a higher upper limit of neutrophil values occurs (Schmutz et al., 2008).

In approximately two-thirds of infants with sepsis, the total neutrophil count is abnormal. Neutropenia is the best predictor of sepsis, whereas neutrophilia does not correlate well. The absolute neutrophil band count is not a sensitive marker of sepsis but has a relatively good predictive value and specificity. The I/T ratio is considered to have the best sensitivity of all of the neutrophil indices (Table 39.2; Gerdes, 2004).

Platelet Counts

Approximately 25%–30% of infants exhibit thrombocytopenia at the time of diagnosis of sepsis, and the frequency increases during the course of infection. Accelerated platelet destruction and possibly

depressed production caused by bacterial products on the bone marrow are the underlying mechanisms for thrombocytopenia in infected infants. Disseminated intravascular coagulation may be seen in some infants with severe sepsis.

Acute-Phase Reactants and Erythrocyte Sedimentation Rate

A number of acute-phase reactants have been studied to help identify infants with likely sepsis. Most biochemical markers currently in use are derived from components of the complex inflammatory response to an invading pathogen. These markers have been studied during the past 20 years and continue to be investigated. The availability of tests for these inflammatory mediators and the value of these tests in assisting with the early diagnosis of neonatal sepsis are both concerns. It is known that the levels of some proinflammatory cytokines peak rapidly, within 1–4 hours after a sepsis stimulus (Lam and Ng, 2008). Among the early markers are the proinflammatory mediators IL-1 β , IL-6, the chemokine IL-8, TNF- α , and interferon gamma; these activate host defenses against bacterial and other infecting agents, whereas antiinflammatory mediators such as IL-4, IL-10, and transforming growth factor β 1 are important in regulating and limiting the inflammatory response, thus preventing an excessive reaction that could lead to organ damage and tissue cell death (Mehr and Doyle, 2000). C-reactive protein (CRP) is induced by proinflammatory cytokines (Hofer et al., 2012), and its level rises to a maximum at 12–24 hours. Procalcitonin (PCT) concentration rises at 4 hours, peaks at 6 hours, and plateaus 8–24 hours after a stimulus. The advantages of having a readily available surrogate marker for sepsis are apparent because of the limitations of WBC counts in predicting neonatal sepsis.

CRP is probably the most studied acute-phase reactant in neonatal sepsis (Weitkamp and Aschner, 2005; Lam and Ng, 2008; Hofer et al., 2012). Monitoring CRP levels has been widely promulgated as a way to diagnose neonatal infection and to adjust the duration of antibiotic therapy in infants with suspected versus proven sepsis (Philip and Mills, 2000; Gerdes, 2004). Depending on the laboratory, a CRP value of 1–8 mg/dL is considered the upper limit of normal; it is important to know the cutoff values in the laboratory supporting one's neonatal units. However, CRP concentration also rises physiologically during the 3 days after birth, and therefore use of serial CRP or higher than normal cutoff values may be more appropriate (Weitkamp and Aschner, 2005;

TABLE 39.2

Predictive Values of Components of the White Blood Cell Count and of C-Reactive Protein Concentration

| Laboratory Result | Sensitivity (%) | Specificity (%) | PREDICTIVE VALUE (%) | |
|--|-----------------|-----------------|----------------------|----------|
| | | | Positive | Negative |
| ANC <1750 cells/ μ L | 38–96 | 61–92 | 20–77 | 96–99 |
| ANC <10% (\approx 5580 cells/ μ L for term) | 48 | 73 | 4 | 98 |
| I/T ratio \geq 0.2 | 90–100 | 30–78 | 11–51 | 98 |
| I/T ratio \geq 0.3 | 35 | 89 | 7 | 98 |
| CRP level >1 mg/dL | 70–93 | 78–94 | 27 | 100 |

ANC, Absolute neutrophil count; CRP, C-reactive protein; I/T, immature neutrophil to total neutrophil ratio.

Modified from Gerdes JS. Diagnosis and management of bacterial infections in the neonate. *Pediatr Clin North Am.* 2004;51:939–959.

Hofer et al., 2012). Theoretically, results can be available within 30 minutes.

CRP is produced by the liver in response to stimulation by the proinflammatory cytokine IL-6, which is produced by both T and B cells (Weitekamp and Aschner, 2005; Lam and Ng, 2008). Because exposure of the host to bacterial products results in a substantial and rapid increase in IL-6 concentrations, it appears that IL-6 is potentially a more useful marker than CRP during the early phase of an infection. In one study, the IL-6 concentration had a sensitivity of 89%, versus 60% for CRP, at the onset of clinical suspicion of a neonatal infection (Lam and Ng, 2008). The negative predictive values for IL-6 are much higher than those for CRP (Lam and Ng, 2008), and this was also found for umbilical cord blood IL-6 levels, where the sensitivity of detection was high. This finding could be useful in deciding which infants do not require antibiotic therapy and those in whom antibiotic therapy can be discontinued after a relatively short course.

High-sensitivity CRP (hsCRP) measurement has been shown to provide increased sensitivity for detecting neonatal infection (Edgar et al., 2010). Not all diagnostic laboratories can provide hsCRP values in a timely fashion. In addition, the optimum diagnostic cutoff levels for CRP and hsCRP are debatable. Serum soluble intercellular adhesion molecule 1 (sICAM-1), hsCRP, soluble E-selectin (sE-selectin), and serum amyloid A, individually and in combination, have been studied for the diagnosis of sepsis in a neonatal intensive care unit (Edgar et al., 2010). In that study, all four measurements had some diagnostic value for neonatal infection; however, sICAM-1, hsCRP, and sE-selectin demonstrated the highest negative predictive value individually (sICAM-1, 84%; hsCRP, 79%; and sE-selectin, 74%) (Edgar et al., 2010). Use of a combination of these measurements enhanced the diagnostic value, with sensitivities of 90.3% and a negative predictive value of 91.3% (Edgar et al., 2010). However, the application of this set of diagnostic markers is not available for most facilities, and more investigative work is needed to confirm their role in excluding early-onset infection.

In another study, early markers (IL-6, TNF- α , IL-8, interferon gamma, CRP, IL-18, the antiinflammatory cytokine IL-10, the I/T ratio, and PCT, a later marker of infection) were studied for use in detection of early-onset sepsis in 123 newborns (Bender et al., 2008). The study concluded that IL-6 combined with PCT was a fair measure for evaluating early-onset infection and that the traditional I/T ratio was almost as efficient as IL-6. Combining an early marker such as IL-6 and an I/T ratio may reduce the number of diagnostic tests and inconclusive values. The combined value of IL-6 and PCT at the first blood drawing had a sensitivity of 71% and a specificity of 88% (Bender et al., 2008).

There are many studies of PCT in the literature, and most have concluded that PCT levels are superior to CRP levels in the early diagnosis of neonatal sepsis (Lam and Ng, 2008). PCT is the precursor of calcitonin, normally synthesized in the C cells of the thyroid gland. PCT is induced by systemic inflammation and bacterial sepsis and is produced by cells such as hepatocytes, nephrons, and monocytes. The physiologic function of PCT is unknown. In bacterial infections, plasma PCT concentrations increase from 0.001–0.01 ng/mL at the baseline to values ranging from 1–1000 ng/mL. PCT concentrations rise much faster than CRP concentrations (6–8 hours versus 48 hours for maximum levels). In healthy newborns, plasma PCT concentrations increase gradually after birth, reaching peak levels at approximately 24 hours of age (range 0.1–20 ng/mL) and then decrease to normal values of less than 0.5 ng/mL by 48–72 hours of age (Stocker

et al., 2010). Various studies on the use of PCT as a marker of neonatal sepsis have yielded contradictory results regarding its application to clinical decision making for both diagnosis and adjustment of the length of antibiotic therapy. In a study of 121 newborns with suspected early-onset sepsis, serial PCT concentration determinations allowed the duration of antibiotic therapy to be shortened (Stocker et al., 2010). PCT and IL-6 were also reported to be the best markers for sepsis in umbilical cord samples (Su et al., 2014). Larger studies are needed to determine the value of PCT in diagnosis and therapy.

To date, studies on the role of various cytokine determinations in assisting with diagnosis and treatment of early-onset sepsis are intriguing, but there has not been translation to widespread use because of a lack of clear efficacy. Other molecular technologies are also being studied to diagnose neonatal sepsis by the rapid identification and differentiation of gram-negative and gram-positive bacterial bloodstream infections. PCR, using universal bacterial primers, targets conserved regions of the 16S ribosomal RNA gene common to all bacteria but not found in other organisms (Dutta et al., 2009). In one study, universal primer PCR was performed in newborns with clinically suspected sepsis. PCR was performed before antibiotic therapy was started and was repeated at 12, 24, and 48 hours after drug therapy had started (Dutta et al., 2009). The sensitivity, specificity, and positive and negative predictive values of universal primer PCR were 96.2%, 96.3%, 87.7%, and 98.8%, respectively. The results of testing in two patients were blood culture positive but 0-hour PCR negative, and the results in seven patients were 0-hour PCR positive, but the blood culture result was negative. Of the patients with a 0-hour PCR-positive result, seven remained positive at 12 hours but none remained positive at 24 and 48 hours after starting antibiotic therapy. Although universal bacterial primer PCR may be a useful test for diagnosing an early episode of culture-proven sepsis, it cannot be used for diagnosis if the patient has been exposed to antibiotic therapy for 12 hours or more (Dutta et al., 2009). Again, larger studies are required before this assay can be recommended for routine clinical use in newborns suspected of having sepsis.

Prevention

Intrapartum Management of Parturients

The universal GBS screening strategy recommended by the CDC is performed at 35–37 weeks' gestation. Antepartum antibiotic therapy is recommended for women with a previous infant with invasive GBS disease, a positive GBS screening culture result during pregnancy, unknown GBS status (culture either not performed or incomplete or results unknown), and any of the following features: delivery before 37 weeks' gestation, rupture of chorioamniotic membranes for more than 18 hours, intrapartum temperature of 38°C or higher, and GBS bacteriuria during pregnancy.

Women who are not allergic to penicillin can be given penicillin G (5,000,000 units as a loading IV dose followed by 2.5 million units every 4 hours until delivery) or ampicillin (2 g IV as a loading dose followed by 1 g every 4 hours until delivery). For women who are allergic to penicillin, the recommendation is to determine, ideally during prenatal care, whether the patient is at high risk of anaphylaxis (i.e., history of immediate hypersensitivity reactions). Women who are not at high risk of anaphylaxis can receive cefazolin (2 g IV and 1 g IV every 8 hours until delivery). Women who are at high risk of anaphylaxis whose GBS isolate is not resistant to clindamycin or erythromycin can receive clindamycin (900 mg

IV every 8 hours until delivery) or erythromycin (500 mg IV every 6 hours until delivery) (Centers for Disease Control and Prevention, 2010). Women with clindamycin–erythromycin–resistant GBS isolates can receive vancomycin (1 g IV every 12 hours until delivery).

There were initial concerns about adverse effects of implementing the CDC consensus strategies, but these have proved unwarranted. The primary risks considered were maternal anaphylaxis from administered antibiotics, and these were unfounded. The possibility of the emergence of infections in mothers and infants caused by antibiotic-resistant organisms (e.g., *E. coli*) has also been addressed. In 2002 the Neonatal Network of the National Institute of Child Health and Human Development reported a change in the pathogens causing early-onset sepsis, with an increase in sepsis caused by *E. coli* from 3.2–6.8 per 1000 live births (Stoll et al., 2002). Most of the *E. coli* isolates were resistant to ampicillin. In another study comparing a period of no prophylaxis with periods of risk-based and universal screening–based prophylaxis, no change in the incidence of infection with ampicillin-resistant organisms was observed overall or among VLBW infants (Puopolo and Eichenwald, 2010). However, an increased proportion of infections was caused by ampicillin-resistant organisms. Mothers of infants with ampicillin-resistant infections were also more likely to have been treated with ampicillin (Stoll et al., 2002; Chen et al., 2005). A 10-year study of the effect of intrapartum antibiotic prophylaxis on GBS and *E. coli* sepsis in Australasia revealed a steady decline in the rate of early-onset GBS infection and a trend to decreasing incidence of early-onset *E. coli* sepsis in all infants and a stable rate for this infection in VLBW infants (Daley et al., 2004).

Intravenous Immune Globulin for Prevention of Early-Onset Sepsis

Premature infants are susceptible to early-onset sepsis because of diminished transplacental transfer of immunoglobulins and decreased synthesis of immunoglobulin G. An IV infusion of immune globulin will increase the typically low levels of serum immunoglobulin in preterm infants, and it has been proposed to improve immune function, which may lead to improved clinical outcome (Wynn et al., 2009). Clinical trials examining the possible benefit of intravenous immune globulin (IVIG) began more than 15 years ago (Haque et al., 1986; Chirico et al., 1987; Conway et al., 1990). A Cochrane metaanalysis showed no reduction in mortality or major disability at 2 years of age for newborns treated with IVIG for what were subsequently proved to be bacterial infections (mortality relative risk 0.95, 95% confidence interval 0.74–1.21; Ohlsson and Lacy, 2015). Currently available data do not support the suggested immunologic enhancements expected for IVIG in premature neonates.

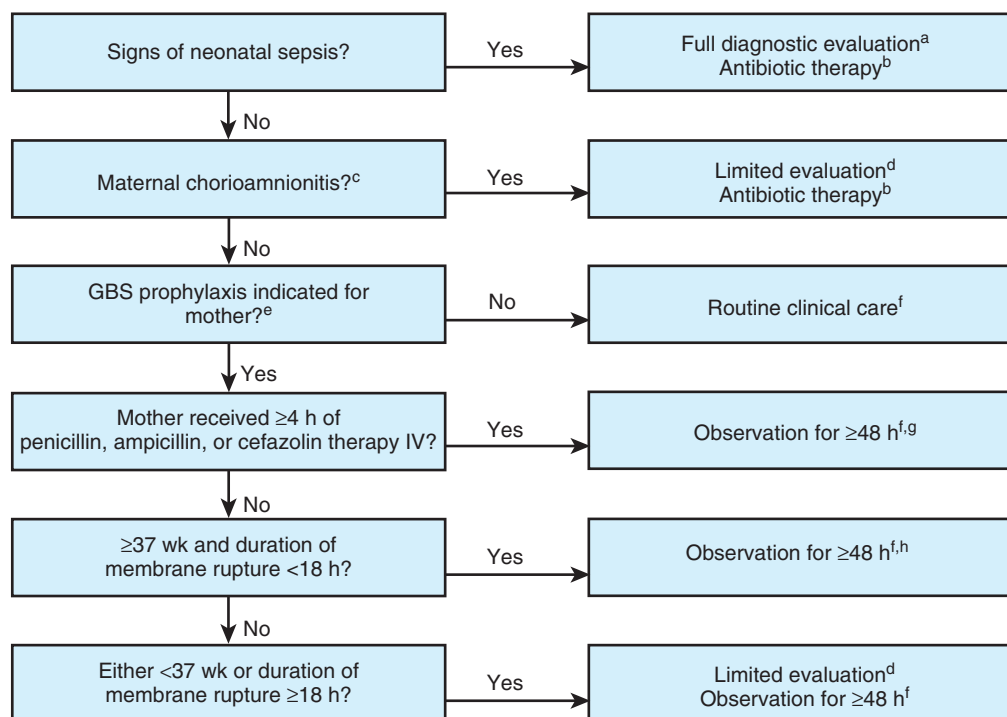

Other immunomodulating factors such as granulocyte colony-stimulating factor (G-CSF) have been studied to both prevent and treat neonatal sepsis. A Cochrane metaanalysis concluded that prophylaxis with G-CSF does not significantly reduce mortality in all infants, although in premature infants with neutropenia (ANC <1750) mortality may be reduced (Carr et al., 2009). It is possible that combination therapies using IVIG and other immunomodulating factors, such as granulocyte–macrophage colony-stimulating factor (GM-CSF), G-CSF, and complement-containing blood products, may lead to improved immune function in these highly susceptible infants; however, such studies are not currently being conducted.

Diagnostic Approach to Neonates With Suspected Sepsis

Obviously, all symptomatic newborns must be carefully evaluated for the possibility of bacterial sepsis and treated with antibiotics, if necessary. Although the presence of various risk factors should increase the suspicion of sepsis, the absence of risk factors in the symptomatic infant does not indicate that sepsis risk can be dismissed. In adjusting to postnatal life, some newborns exhibit abnormal signs transiently, such as tachypnea, before becoming asymptomatic. However, in any newborn who has other findings or is still symptomatic 6 hours after birth, a diagnostic evaluation with a complete blood cell count and differential, a blood culture, and, as appropriate, a lumbar puncture and a chest radiograph should be strongly considered. Antibiotic therapy can be stopped when the physical findings are normal, the clinical suspicion of sepsis is low, and the screening results for sepsis, including the blood culture results, remain negative. If the blood culture result is positive, the lumbar puncture findings abnormal, or there are clinical signs of sepsis, then the newborn should be treated with an appropriate course of antibiotics.

Treatment of the asymptomatic infant with risk factors for sepsis is much more controversial. The 2010 CDC guideline recommended that all infants born to mothers with a diagnosis of chorioamnionitis be evaluated for sepsis and treated with antibiotics for 48 hours (Fig. 39.2; Polin and Committee on Fetus and Newborn, 2012; Brady and Polin, 2013). One of the major difficulties in implementing this recommendation is a lack of standard definition of chorioamnionitis (Higgins et al., 2016). In addition, a number of analyses suggested that fewer infants would be treated with antibiotics if specific risk factors and the infant's clinical status are considered. Escobar et al. (2000) retrospectively reviewed 2785 newborns with birth weight greater than 2000 g and who were evaluated for sepsis after birth. Asymptomatic status was associated with a significantly decreased odds ratio for infection. Further analysis identified the most predictive factors for early-onset sepsis to be highest intrapartum maternal temperature, duration of rupture of membranes, gestational age, maternal GBS status, and intrapartum antibiotic use (Puopolo et al., 2011). Subsequent studies showed that following the CDC guidelines resulted in asymptomatic infants being treated with antibiotics for 48 hours or more with no clear evidence of benefit (Benitz et al., 2015). In addition, the use of ancillary tests such as the complete blood cell count and CRP concentration as predictors of sepsis in these asymptomatic infants resulted in many infants with negative culture results being treated with antibiotics for 5–7 days (Brady and Polin, 2013; Kiser et al., 2014; Polin et al., 2014).

Combining the objective risk factors found to be most highly associated with neonatal sepsis (Puopolo et al., 2011) with the newborn physical examination over the first 12 hours led to the development of a neonatal sepsis risk calculator to guide evaluation and therapy of the late preterm and term infant who has maternal risk factors for sepsis (Escobar et al., 2014). The current version of the neonatal early-onset sepsis calculator (<https://neonatalesepsiscalculator.kaiserpermanente.org/>) includes definitions of clinical status, including clinical illness, equivocal symptoms, and well appearing. Combining clinical status with maternal risk factors, the calculator provides a numerical estimate of the risk of sepsis and a clinical recommendation for management and monitoring. Use of the neonatal sepsis calculator has the benefit of reducing unnecessary antibiotic exposure and provides a model

• **Fig. 39.2** Secondary Prevention of Group B Streptococcus Disease. Algorithm for the prevention of early-onset group B streptococcus (GBS) infection in the newborn. *Superscript a* indicates full diagnostic evaluation including a blood culture; complete blood cell (CBC) count, including white blood cell differential and platelet counts; chest radiograph (if respiratory abnormalities are present); and lumbar puncture (if the patient is stable enough to tolerate the procedure and sepsis is suspected). *Superscript b* indicates antibiotic therapy should be directed toward the most common causes of neonatal sepsis, including intravenous ampicillin therapy for GBS infection and coverage for infection by other organisms (including *Escherichia coli* and other gram-negative pathogens) and should take into account local antibiotic-resistance patterns. *Superscript c* indicates consultation with obstetric providers is important in determining the level of clinical suspicion for chorioamnionitis. Chorioamnionitis is diagnosed clinically, and some of the signs are nonspecific. *Superscript d* indicates limited evaluation, including blood culture (at birth) and CBC count with differential and platelet counts (at birth and/or at 6–12 hours after birth). *Superscript e* indicates GBS prophylaxis is indicated if one or more of the following are true: (1) the mother is GBS-positive late in gestation and is not undergoing cesarean delivery before labor onset with intact amniotic membranes; (2) GBS status is unknown and there are one or more intrapartum risk factors, including less than 37 weeks' gestation, rupture of membranes for 18 hours or more, or temperature of 38.0°C or greater; (3) GBS bacteriuria during current pregnancy; or (4) history of an infant with GBS disease. *Superscript f* indicates that if signs of sepsis develop, a full diagnostic evaluation should be performed, and antibiotic therapy should be initiated. *Superscript g* indicates that if the stage is 37 weeks' gestation or later, observation may occur at home after 24 hours if other discharge criteria have been met, there is ready access to medical care, and a person who is able to comply fully with instructions for home observation will be present. If any of these conditions are not met, the newborn should be observed in the hospital for at least 48 hours and until discharge criteria have been achieved. *Superscript h* indicates that some experts recommend a CBC count with differential and platelet counts at 6–12 hours of age. IV, Intravenously; wk, weeks. (From Centers for Disease Control and Prevention. Prevention of perinatal group B streptococcal disease – revised guidelines from CDC. *MMWR Recomm Rep*. 2010;59(RR-10):1–36. Reproduced with permission from Brady MT, Polin RA. Prevention and management of infants with suspected or proven neonatal sepsis. *Pediatrics*. 2013;132:166–168. Copyright 2013 American Academy of Pediatrics.)

that can be updated as new data become available (Kuzniewicz et al., 2016).

In addition to the neonatal sepsis calculator, the National Institute of Child Health and Human Development has recently published the results of a workshop to provide evidence-based guidelines for diagnosis and management of pregnant women and their neonates at risk of infection because of the condition commonly called chorioamnionitis (Higgins et al., 2016). The workshop summary explicitly addressed the lack of a clinical definition of chorioamnionitis that caused wide variability in the use of this

diagnosis to encompass heterogeneous conditions involving both inflammation and infection. The panel recommends replacing the diagnosis of chorioamnionitis with a classification of “intrauterine infection or inflammation or both,” which it calls “Triple I.” The summary provides detailed definitions of maternal fever and other parameters and recommends dividing maternal fever into three categories: isolated fever, suspected Triple I, and confirmed Triple I. Suspected Triple I is defined as fever without a source combined with baseline fetal tachycardia, maternal WBC count greater than 15,000, and/or purulent fluid from the cervical os. Confirmed Triple

It requires symptoms compatible with suspected Triple I plus biologic or microbiologic amniotic fluid results consistent with microbial invasion of the amniotic cavity. The final recommendations of the workshop included no empiric treatment of the “well-appearing” neonate born at more than 33 completed weeks of gestation, and use of the neonatal sepsis calculator to help with decisions about treatment is mentioned (Higgins et al., 2016).

Recent CDC and American Academy of Pediatrics (AAP) guidelines for the prevention of early-onset neonatal GBS sepsis have a different approach to management of the at-risk asymptomatic infant (see Fig. 39.2; Centers for Disease Control and Prevention, 2010; Brady and Polin, 2013). If there are signs of sepsis in the newborn, then a full sepsis work-up and antibiotic therapy are recommended. If there is maternal chorioamnionitis, a limited sepsis evaluation and antibiotic therapy are recommended. In the asymptomatic infant with a negative blood culture result, consideration should be given to stopping antibiotic therapy after 48–72 hours, even if screening test results were abnormal (Polin et al., 2014). For infants whose mother received antibiotic therapy for GBS positive status for more than 4 hours, it is recommended that the infant be observed in the hospital for 24–48 hours. For infants whose mother did not receive antibiotic prophylaxis for more than 4 hours, a 48-hour in-hospital observation is recommended. If the infant was born at less than 37 weeks’ gestation, or the duration of rupture of membranes is greater than or equal to 18 hours, then a limited evaluation and observation in the hospital for approximately 48 hours are recommended. The CDC and AAP guidelines advocate wider antibiotic use and longer in-hospital observation for asymptomatic newborns than the risk-based neonatal sepsis calculator described earlier and are likely to be revised soon. The reader is advised to look for the most up-to-date CDC and AAP guidelines.

Treatment

Antimicrobial Therapy

The choice of antibiotic for an infant with suspected early-onset sepsis depends on the predominant bacterial pathogens and the antibiotic susceptibility profiles for the microorganisms causing early-onset disease in a particular geographic region. Any decision to discontinue antimicrobial therapy should be based on the level of suspicion for sepsis at the time treatment was begun, the culture results, laboratory test results, and the clinical behavior and course of the infant. If sepsis is highly suspected in an infant, antibiotics should be considered for a full course even if the culture results are negative.

Empiric therapy for early-onset sepsis generally consists of combinations of antibiotics effective against gram-positive pathogens (e.g., GBS, *L. monocytogenes*) and gram-negative pathogens (e.g., *E. coli*). The two most commonly used combinations are (1) ampicillin with an aminoglycoside, usually gentamicin, and (2) ampicillin with a third-generation cephalosporin, usually cefotaxime. Cefotaxime has minimal toxicity and is well tolerated by newborns. However, the third-generation cephalosporins, as well as vancomycin, a glycopeptide antibiotic, have been associated with the development of vancomycin-resistant enterococci and, in the case of cephalosporins, with the induction of various β -lactamase-producing gram-negative bacteria, including extended-spectrum β -lactamase-producing organisms (de Man et al., 2000). These latter bacteria are resistant to all β -lactam antibiotics and are frequently resistant to other antibiotics, but not to meropenem. Another disadvantage

of the cephalosporin antibiotics is the lack of effectiveness against enterococci or *L. monocytogenes*. *L. monocytogenes* is usually treated with ampicillin and an aminoglycoside until the blood culture result is negative and the infant has shown an improved outcome. In infants with bacteremia and sepsis caused by GBS, gentamicin is frequently combined with ampicillin or penicillin, although there are no data to suggest that the addition of the aminoglycoside improves outcome. However, it is common practice to use the combination of these two drugs during the first few days of therapy and then to continue the full course of therapy with ampicillin or penicillin alone.

When the likelihood of infection is very low, the antibiotic therapy should be stopped. In most hospitals using modern blood culture instrumentation, 48 hours is sufficient to determine whether a blood culture result is negative, assuming that no antibiotics were being given when the culture was obtained (García-Prats et al., 2000; Jardine et al., 2006). Blood culture bottles with antimicrobial binding resins are in common use in microbiology laboratories, enhancing the ability to demonstrate positive blood culture results. Infants with proven bacteremia, but without meningitis, are commonly treated for 7–10 days. The use of antibiotics with nephrotoxicity (i.e., aminoglycosides) should be monitored with the use of appropriate drug levels.

Immunologic Therapies for Early-Onset Sepsis

Various adjunctive therapies have been proposed to improve the immune status of the newborn in an attempt to reduce neonatal sepsis mortality. These included IVIG, granulocyte transfusions, and G-CSF or GM-CSF treatment. Overall there are insufficient data to recommend the routine use of any of these therapies for the treatment of sepsis in newborns. Mortality in cases of subsequently proven infection was not reduced in the IVIG-treated newborns (Ohlsson and Lacy, 2015), and clinical studies also did not show that granulocyte transfusions provided a significant benefit to neonates with culture-proven early-onset infections (Vamvakas and Pineda, 1996).

Use of GM-CSF and G-CSF to enhance the quantity and quality of neutrophils has also been studied in human neonates (Carr et al., 2009). Although these agents have induced circulating numbers of neutrophils and appeared to be relatively safe, they have not significantly reduced neonatal sepsis mortality (Wynn et al., 2009). In two metaanalyses, subgroup analysis showed a significant reduction in mortality in the group of infants with systemic infection and neutropenia (Bernstein et al., 2001; Carr et al., 2009). Future studies may prove that selective use of these therapies is beneficial in specific subgroups of septic infants.

Neonatal Bacterial Meningitis

Neonatal bacterial meningitis is ominous because of the associated mortality and morbidity. Meningitis is associated with the same pathogens that cause bacterial sepsis, with GBS and *E. coli* accounting for approximately 70% of all cases and *L. monocytogenes* accounting for an additional 5% in the first week of life. On occasion, it is possible to isolate *S. pneumoniae* and *H. influenzae*, and in newborns who are older than 1 week residing in neonatal intensive care units, coagulase-negative staphylococci are the most common isolates. The underlying pathogenesis of bacterial meningitis is a seeding of the meninges during a bacteremic phase in the newborn. Studies in neonatal rats have shown that high-grade

bacteremia is more likely than low-grade bacteremia to lead to bacterial meningitis.

GBS meningitis (with mortality approaching 30% and morbidity of 50%) usually presents as late-onset disease, and the most common GBS serotype identified is III (Levent et al., 2010). Ansong et al. (2009) reported that GBS meningitis complicated 22 of 145 episodes (15%) of early-onset GBS sepsis and 13 of 23 episodes (57%) of late-onset GBS sepsis. GBS meningitis can occur in the presence of negative blood culture results, and 20% of infants in the study had negative blood culture results (Ansong et al., 2009).

Approximately 80% of all serotypes of *E. coli* that cause meningitis in newborns possess the K1 or capsular antigen. The K1 capsular polysaccharide antigen is considered one of the primary virulence factors of this capsular type of *E. coli*, because antibody against K1 antigen has been shown to be protective in neonatal rat models of infection. Mortality rates for neonatal *E. coli* meningitis range from 20%–30% in some centers and from 50%–60% in others (Dodge, 1994).

Pathology and Clinical Manifestations

At autopsy, infants who die of meningitis have purulent exudates of the meninges and the surfaces of the ventricles associated with inflammation. Historically, hydrocephalus and a noninfectious encephalopathy were demonstrated in approximately 50% of infants who died of bacterial meningitis.

The signs and symptoms of neonatal meningitis are not easy to distinguish from those of sepsis. The most common presenting symptoms are lethargy, feeding problems, instability of temperature regulation, vomiting, respiratory distress, and apnea. A bulging fontanel may be seen, but this is usually a late manifestation. Seizures are frequently observed and can be caused by either direct central nervous system inflammation or by metabolic abnormalities such as hypoglycemia or hyponatremia.

Diagnosis

The gold standard for diagnosis of meningitis is the analysis of the CSF, including the WBC count, glucose and protein levels, Gram stain, and culture. The interpretation of CSF cell counts in newborns may be difficult (Garges et al., 2006; Greenberg et al., 2008). During the first week of life the CSF WBC count slowly decreases in term newborns but may remain high or even increase in premature newborns. There is no change in CSF WBC counts or protein content with gestational age, but there is a significant decrease with postnatal age (Mhanna et al., 2008). The 95th percentile for CSF WBC count is reported to be 19/ μ L, but individual infants with no proven infection had higher WBC counts ranging from 75–100/ μ L (Ahmed et al., 1996; Kestenbaum et al., 2010). The cell counts, protein concentrations, and glucose concentrations from healthy infants may overlap with those from infants with meningitis, and 1%–10% of infants with proven meningitis have normal results on CSF analysis (Hristeva et al., 1993; Garges et al., 2006; Greenberg et al., 2008). Finally, approximately 30% of all infants with positive results of CSF cultures for bacteria have negative blood culture results (Wiswell et al., 1995; Garges et al., 2006).

A Gram stain of CSF must be examined carefully for every infant with suspected meningitis. The stains for approximately 20% of newborns with proven meningitis are reported as showing “no bacteria seen.” Although an increase is expected in the number of neutrophils with bacterial meningitis, one may see a predominance

of lymphocytes within a conversion to PMNs. With *L. monocytogenes*, a mononuclear cellular response is found on examination of the CSF. In clinical care units, it is routine to repeat the CSF examination and culture 2–3 days after the initiation of antibiotic therapy. This examination is especially important if the patient has not responded clinically and is experiencing seizures or continued fever. At times it is difficult to eradicate the organism from the CSF, and consideration can be given to examining the inhibitory and bactericidal concentrations in CSF. It is especially important to repeat the CSF examination before antibiotic therapy is stopped in patients with more complicated courses and for enteric gram-negative bacterial meningitis.

Therapy

Infants with bacterial meningitis are frequently ill and should be monitored in intensive care units, where the critical needs can be met with aggressive management. These patients may require mechanical ventilation, complex fluid management to attenuate the effects of cerebral edema and effects of secretion of inappropriate antidiuretic hormone, seizure control, vasopressor support, and cardiopulmonary monitoring. The choice of appropriate antibiotic therapy is based on several factors, including the achievable CSF levels of drugs that have in vitro efficacy against the microorganism. In the case of gram-positive bacteria, the use of penicillin and ampicillin will achieve 10–100-fold higher concentrations than the minimal inhibitory concentrations needed to inhibit the bacteria, and there is rapid sterilization of the CSF. In contrast, aminoglycosides, such as gentamicin and tobramycin, achieve only 40% of peak serum levels and may not achieve minimal inhibitory concentrations more than those equal to or slightly greater than found in vitro for gram-negative bacteria.

In many intensive care units, ampicillin and gentamicin are recommended as initial therapy for neonatal meningitis. An alternative regimen of ampicillin and cefotaxime can also be used, recognizing the potential for the introduction of cephalosporin-resistant gram-negative isolates in the unit. Although used in the past, neither intrathecal nor intraventricular administration of antibiotics has been found to reduce the morbidity or mortality associated with gram-negative meningitis (Shah et al., 2008). Once the microorganism has been identified and the antibiotic susceptibility results are available, either a single drug or a combination of drugs found to be effective in vitro should be used. Usually penicillin or ampicillin is used for GBS meningitis; in the first few days of therapy, dual therapy with an aminoglycoside may be used. It is common to treat *L. monocytogenes* infection with ampicillin with or without gentamicin. Ampicillin or cefotaxime with or without an aminoglycoside can be used for infection with gram-negative enteric bacteria. The precise length of antibiotic therapy depends on the rapidity of response and sterilization of CSF. In general, therapy should be continued for approximately 2 weeks after sterilization of the CSF or a minimum of 2 weeks for gram-positive meningitis and a minimum of 3 weeks for gram-negative meningitis. In difficult situations, therapy may be required for as long as 4–6 weeks. A Cochrane review of two trials of adjuvant corticosteroids in neonatal bacterial meningitis suggested a reduction in death and hearing loss with steroid therapy, but there was no reduction in neurologic sequelae at 10 weeks. Both trials were small, and further study is necessary before steroid use can be routinely recommended (Ogunlesi et al., 2015).

It may be prudent to repeat a CSF examination and culture after initiation of therapy, especially if the clinical response is less

than satisfactory. If organisms are seen on gram-stained smears of the fluid, modification of the therapeutic regimen should be considered. In general, approximately 3 days or more is required for an antibiotic regimen to sterilize the CSF in infants with gram-negative meningitis. In infants with gram-positive meningitis, sterilization is usually seen within 36–48 hours. Neuroimaging should be considered to exclude parameningeal foci and abscess formation and to assist in assessing the infant's prognosis.

Prognosis

Complications from neonatal meningitis include brain abscess, communicating or noncommunicating hydrocephalus, subdural effusions, ventriculitis, deafness, and blindness. Generally, the severity of complications is related to the severity of the disease during the early neonatal period. It is imperative to follow hearing competency and to examine these infants for prolonged periods after recovery. The infant who has experienced meningitis may appear relatively healthy at the time of discharge, and only after careful follow-up do perceptual difficulties, reading problems, or signs of brain damage become apparent. Approximately 40%–50% of survivors have some evidence of neurologic damage, with severe damage being obvious in 11%. Infants who survive neonatal meningitis should have regular audiology, language, and neurologic evaluations until they enter school (Edwards et al., 1985; Stevens et al., 2003).

Health Care-Associated Infections

LAKSHMI SRINIVASAN AND JACQUELYN R. EVANS

KEY POINTS

- Health care–associated infections (HAIs) are an important preventable cause of morbidity and death in neonates.
- Central line–associated bloodstream infections cause the bulk of neonatal intensive care infections; other HAIs include ventilator-associated pneumonias, urinary tract infections, skin and soft tissue infections, and nosocomial viral infections.
- Several modifiable risk factors have been identified for these conditions. Preventive strategies must focus on basic hand hygiene and infection control measures, along with specific measures for the infection.
- In recent years quality improvement collaboratives have achieved great strides in infection reduction by developing improved surveillance and benchmarking strategies and implementation of bundles of preventive measures.

Health care–associated infections (HAIs) are infections acquired by patients during hospitalization. For decades HAIs have been considered an unavoidable problem in the neonatal intensive care unit (NICU). Several factors converge to create a high risk of infection in the NICU patient: immature innate and adaptive immune defenses, the need for life-sustaining invasive interventions, broad-spectrum antibiotic exposure, and prolonged hospital stays associated with colonization with potentially pathogenic microorganisms (Stoll et al., 2002; Edwards et al., 2009; Polin et al., 2012b). The growing frequency of surviving very low birth weight (VLBW) infants and the use of invasive technologies magnify the impact of this problem. HAIs have been shown to significantly and independently impact neonatal outcomes, including death, short-term and long-term morbidities, hospital length of stay, and healthcare costs (Payne et al., 2004; Stoll et al., 2004a; Adams-Chapman et al., 2006; Shah et al., 2008; Bassler et al., 2009; Schlapbach et al., 2011; de Haan et al., 2013; Donovan et al., 2013; Mitha et al., 2013).

Clinicians can minimize HAIs by consistently and reliably following best practices for infection prevention and minimizing invasive procedures to the extent possible. Continuous surveillance

and monitoring of HAI rates and the patterns of the pathogens responsible are necessary to establish reference points in each nursery and facilitate early identification of epidemics. Prevention of infections in neonates requires a modified and expanded set of measures in addition to organized hospital-wide initiatives. Quality improvement strategies, standardization of practice, and hospital programs such as antimicrobial stewardship are all essential to preventing harm. In recent years many centers have used these strategies to reduce the burden of HAIs, some with great success (Andersen et al., 2005; Schulman et al., 2011; Wirtschafter et al., 2011; Payne et al., 2012; Fisher et al., 2013; Shepherd et al., 2015). In this chapter we will review the data sources, definitions, epidemiology, and adverse outcomes related to HAI, as well as current concepts and evidence surrounding strategies for prevention of HAI in NICUs.

Health Care–Associated Infection Surveillance and Data Sources

Sources of data on neonatal HAIs in the United States include the Centers for Disease Control and Prevention (CDC), the National Healthcare Safety Network (NHSN), the Vermont Oxford Network (VON), the National Institute for Child Health and Human Development (NICHD), Neonatal Research Network (NRN), and the Children's Hospitals Neonatal Database (Polin et al., 2012b). Reporting overall incidence rates may be misleading because of wide variations in practice and patient populations; therefore the CDC NHSN system, developed in 2005, monitors device-associated HAI rates by using an approach that accounts for variability in device use and length of hospital stay (Emori et al., 1991; Gaynes et al., 1996; Edwards et al., 2008). These data are also stratified by birthweight categories and expressed as incidence density per 100 or 1000 patient or device days. These adjustments modify the relative risk (RR) on the basis of the severity of the illness and the duration of exposure to the risk factor. NHSN tracks HAIs in more than 17,000 medical facilities and shares the data with the facilities, the CDC, and other partners and quality improvement organizations to help guide efforts at infection prevention. Outside of the United States the International Nosocomial Infection Control Consortium runs a surveillance network for HAIs, using CDC

NHSN definitions, in more than 1000 hospitals around the world, and provides aggregate data on HAI from several countries (Rosenthal, 2016).

Defining and Diagnosing Neonatal Health Care–Associated Infection

The CDC provides the following surveillance definition for HAI: illness associated with a pathogen or its toxins that is not present or incubating at the time of admission (Horan et al., 2008). Although this definition appears straightforward, it leaves some room for confusion in neonates. Infections that manifest themselves early in the first week of life are typically related to perinatal risk factors and vertical transmission from the mother. HAIs are more often related to patient colonization and environmental risk factors. While most sources define HAIs in neonates as infections occurring after 3 days of postnatal life (Baltimore, 1998; Stoll et al., 2002), there is no specific age that clearly distinguishes maternally transmitted infections from HAIs (Baltimore, 1998); there may be substantial temporal overlap between HAIs and late-onset, perinatally acquired infections, such as group B streptococcus, for example. The CDC NHSN currently defines HAIs in neonates as those infections initially identified on day 3 or later and thus includes infections

that may have been acquired perinatally (Horan et al., 2008). Therefore neonatal HAI rates may be slightly overestimated during the first few weeks of life.

Definitions of Central Line–Associated Bloodstream Infection, Ventilator–Associated Pneumonia, and Catheter–Associated Urinary Tract Infection

Definitions of central line–associated bloodstream infection (CLABSI), ventilator-associated pneumonia (VAP), and catheter-associated urinary tract infection (UTI) are given in Box 40.1.

Challenges With Central Line–Associated Bloodstream Infection Diagnosis

While coagulase-negative staphylococci (CoNS) are common skin commensals, they are also the most common cause of CLABSIs in the NICU. Differentiating contamination from true infections with these pathogens is one of the greatest challenges surrounding neonatal CLABSI definitions. The CDC introduced a change to its definition in 2008, namely, the requirement for two blood cultures positive for skin commensals to fulfill the definition of a CLABSI

• BOX 40.1 Definitions of Health Care–Acquired Infections for Patients Younger Than 12 Months (Centers for Disease Control and Prevention National Healthcare Safety Network)

Nosocomial Bloodstream Infections

Laboratory-confirmed bloodstream infection (LCBI). Must meet one of the following definitions:

- Recognized pathogen in one or more blood specimens (culture or nonculture based microbiologic methods), performed for clinical diagnostic or therapeutic purposes *and* not related to infection at another site
- Commensal organism (e.g., coagulase-negative staphylococci, diphtheroids, bacillus, viridans streptococci, aerococcus, micrococcus, propionibacterium), identified from two or more blood specimens obtained on separate instances (culture or nonculture based microbiologic methods), performed for clinical diagnostic or therapeutic purposes *and* not related to infection at another site *and* at least one of the following signs: (1) fever (temperature $>38.0^{\circ}\text{C}$), (2) hypothermia (temperature $<36.0^{\circ}\text{C}$), or (3) apnea or bradycardia

Central line–associated bloodstream infection (CLABSI):

- LCBI (as defined above) *and*
- Central line or umbilical catheter in place for more than 2 days *and*
- Central line in place on day of or day before CLABSI diagnosis

Pneumonia:

- Two or more serial chest radiographs with new/progressive and persistent infiltrate, cavitation, consolidation, or pneumatoceles for patients with underlying pulmonary or cardiac disease (respiratory distress syndrome, bronchopulmonary dysplasia, pulmonary edema) *or* one chest radiograph with the aforementioned abnormalities for patients without underlying pulmonary or cardiac disease *and*
- Worsening gas exchange *and*
- At least three of the following: (1) temperature instability, (2) white blood cell count less than $4000/\mu\text{L}$ or greater than $15,000/\mu\text{L}$ with

10% or more bands, (3) new-onset purulent sputum, change in character of sputum, increased respiratory secretions, or increased suctioning requirements, (4) physical examination findings consistent with increased work of breathing or apnea, wheezing, rales, or rhonchi, (5) cough, (6) bradycardia (<100 bpm), and (7) tachycardia (>170 bpm)

Ventilator-associated pneumonia (VAP):

- Pneumonia (as defined above) *and*
- Patient on ventilator for more than 2 days *and*
- Ventilator in place on day of or day before VAP diagnosis

Urinary Tract Infection

Symptomatic urinary tract infection (SUTI):

- At least one of the following symptoms: (1) fever (temperature $>38.0^{\circ}\text{C}$), (2) hypothermia (temperature $<36.0^{\circ}\text{C}$), (3) apnea, (4) bradycardia, (5) lethargy, (6) vomiting, or (7) suprapubic tenderness *and*
- Urine culture with no more than two species identified, at least one of which is present at more than 10^5 CFU/mL

Asymptomatic bacteremic urinary tract infection (ABUTI):

- Urine culture with no more than two species identified, at least one of which is present at more than 10^5 CFU/mL *and*
- Bacteria identified in blood (culture-based or nonculture-based microbiologic method) that matches at least one of the bacteria present at more than 10^5 CFU/mL in urine

Catheter–associated urinary tract infection:

- Urinary tract infection (as defined above, either SUTI or ABUTI) *and*
- Indwelling urinary catheter for more than 2 days *and*
- Urinary catheter in place on day of or day before urinary tract infection diagnosis

bpm, Beats per minute; CFU, colony-forming unit.

Modified from Horan TC, Andrus M, Dudeck MA. CDC/NHSN surveillance definition of health care-associated infection and criteria for specific types of infections in the acute care setting. Am J Infect Control. 2008;36:309–332.

(Horan et al., 2008). However, the Children's Hospitals Neonatal Database and the VON and NICHD databases include infants with only one culture positive for CoNS in the presence of clinical signs of infection (Polin et al., 2012b). Further, despite clinical practice guidelines recommending the drawing of peripheral and central line cultures, clinicians in the NICU often only obtain a single culture because of various constraints. Also, further refinements of CLABSI definitions (in terms of the timing of infection following hospital admission, line placement, etc.) may impact the number of CLABSIs reported (Farrell et al., 2015; Hazamy et al., 2015). Another area of uncertainty surrounds whether some CLABSIs in infants with underlying gastrointestinal (GI) conditions may result from translocation caused by mucosal barrier injury; studies to date have not fully borne out this hypothesis (see [Risk Factors for Development of Health Care–Associated Infection](#)) (Coffin et al., 2014). Recent studies have demonstrated that International Classification of Diseases, Ninth Revision (ICD-9) coding of hospital administrative data has low concordance with NHSN definitions of CLABSI (Moehring et al., 2013; Patrick et al., 2013). As the Centers for Medicare and Medicaid Services uses ICD-9 codes for case finding, this discrepancy highlights definitional challenges surrounding the policy of the Centers for Medicare and Medicaid Services of reduced payment or nonpayment for hospital-acquired conditions such as CLABSI.

Challenges With Ventilator-Associated Pneumonia Diagnosis

VAP definitions were developed for surveillance purposes, but they are problematic to apply in neonates, as they have not truly been validated as clinical diagnostic criteria (Baltimore, 2003; Garland, 2010; Polin et al., 2012b). Overlap of signs and symptoms and radiographic findings with underlying respiratory conditions poses significant challenges to the diagnosis of VAP in neonates and may lead to overdiagnosis (Baltimore, 2003; Garland, 2010; Polin et al., 2012b). Moreover, microbiologic testing such as respiratory cultures does not reliably distinguish bacteria colonizing the respiratory tract from true infections. Gram stain of respiratory secretions may demonstrate an inflammatory infiltrate with neutrophils, but this may indicate a tracheitis or pneumonia (Salata et al., 1987). If the Gram stain and culture identify the same organism, this strengthens the likelihood of its causal role in the VAP (Salata et al., 1987). Finally, it is challenging to obtain true samples of lower respiratory tract secretions from infants (Barzilay et al., 1988; Allen et al., 1994). Because of these challenges with defining VAP accurately in the neonatal population, in 2014 the NHSN discontinued accepting and analyzing VAP identified in the NICU. However, many NICUs and collaboratives continue surveillance and internal benchmarking of this condition.

Challenges With Urinary Tract Infection Diagnosis

Clinicians often use less stringent microbiologic criteria (ranging from 100 to 10,000 colony-forming units [CFUs] of bacteria per milliliter in urine) for neonatal UTI diagnosis compared with CDC definitions (Bauer et al., 2003; Levy et al., 2009; Clarke et al., 2010). CoNS may be isolated in urine samples, raising the question (similar to bloodstream infections) of whether they represent contamination or true infection (Clarke et al., 2010; Foglia et al., 2012).

Epidemiology of Health Care–Associated Infection

Health Care–Associated Infection Epidemiology in the Newborn Nursery

Accurate rates of HAI in the “well baby” nursery are difficult to ascertain because there is no systematic reporting or surveillance network for this location; however, the incidence appears to be low. Some researchers estimate rates of less than 1 per 100 patients discharged (Baltimore, 1998). Typical risk factors for acquiring an HAI are uncommon in this population. Discharge from the hospital within 48 hours of birth, “baby-friendly” hospital policies, and rooming-in practices have helped to further decrease the risk of exposure in modern mother–baby units. However, early discharge may also limit surveillance efforts and documented rates of HAI, as patients may be discharged home before they become symptomatic from HAIs (Goldmann, 1989).

HAIs in the well baby nursery are commonly superficial, involving the skin, mouth, or eyes, and include omphalitis, pustules, abscesses, and bullous impetigo (Goldmann, 1989). In recent years, community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) has been implicated in outbreaks of skin and soft tissue infections (SSTIs) and pneumonia in newborn nurseries (Alsubaie et al., 2012; Huang et al., 2012; Filleron et al., 2013; Sanchini et al., 2013; Lee et al., 2014). Legionella outbreaks have been reported in term neonates, because of nosocomial contamination from water sources (water births, humidifiers) (Franzin et al., 2001; Yiallourous et al., 2013). Nursery epidemics of other bacterial enteropathogens and viral enteropathogens have been reported but occur infrequently in the United States in the current era (Goldmann, 1989; Syriopoulou et al., 2002; Fuchs et al., 2013).

Health Care–Associated Infection Epidemiology in the Neonatal Intensive Care Unit

Most neonatal HAIs occur in term and preterm infants hospitalized in NICUs. Comparison of surveillance data between institutions needs to be carefully performed because of differences in patient demographics and the use of different definitions for HAI.

Data from the NICHD NRN in 2002 demonstrated that 21% of VLBW infants who survived beyond 3 days postnatally had at least one episode of late-onset sepsis (Stoll et al., 2002). There was significant variability among the participating centers, with rates ranging from 10.6% to 31.7% at individual sites (Stoll et al., 2002). In another study, 19% of VLBW infants had HAIs, with the highest rates in infants with the lowest birthweights (Brodie et al., 2000). A point prevalence survey conducted by 29 level II to level IV nurseries participating in the Pediatric Prevention Network revealed a prevalence of 11.4% for HAI (Sohn et al., 2001). Recent data from the NICHD NRN showed that the rates of late-onset sepsis declined from 2005 to 2012 among VLBW infants of all gestational ages: the rates for infants born at 24 weeks' gestation declined from 54% to 40% (adjusted RR 0.94, 95% confidence interval [CI] 0.93–0.95), for infants born at 26 weeks' gestation the rates declined from 37% to 27% (adjusted RR 0.93, 95% CI 0.92–0.94), and for infants born at 28 weeks' gestation the rates declined from 20% to 8% (adjusted RR 0.91, 95% CI 0.90–0.92) (Stoll et al., 2015).

CLABSIs constitute most of the HAIs in the NICU (Gaynes et al., 1996; Sohn et al., 2001; Dudeck et al., 2013). The remaining cases involve the respiratory tract, eye, ear, nose, throat, GI tract, or urinary tract or may be SSTIs. VAPs are difficult to diagnose in the NICU but can contribute to morbidity, especially in patients with evolving lung disease. Although the use of bladder catheters is low in the NICU compared with other intensive care units, the acquisition of UTIs while the neonate is in the NICU is still a problem. Surveillance data for meningitis are limited. There are widespread differences in clinical practice regarding the inclusion of a lumbar puncture with cerebrospinal fluid analysis in the evaluation for possible neonatal sepsis. While early-onset meningitis is rare, studies suggest that late-onset meningitis may be underdiagnosed in the high-risk population of VLBW infants (Stoll et al., 2004b, 2011).

Rates of device-associated infections in NICUs in the United States are presented in Table 40.1. These rates remained constant in the 1990s (Gaynes et al., 1996; Centers for Disease Control and Prevention, 2000) but appear to have dropped in the late years of the first decade of this century, likely because of the impact of HAI preventive collaborative quality improvement efforts (see Prevention of Health Care–Associated Infection) (Edwards et al., 2009; Schulman et al., 2011; Wirtschafter et al., 2011; Hocevar et al., 2012; Payne et al., 2012; Dudeck et al., 2013; Patrick et al., 2014). While it is encouraging to note that the CLABSI rate decreased from 4.9 to 1.5 per 1000 central line days across 173

US hospitals that provided data to NHSN from 2007 to 2012 (Fig. 40.1), CLABSIs continue to contribute to 25%–60% of HAIs in the neonatal population (Dudeck et al., 2013; Patrick et al., 2014). In addition to the impact of collaborative quality improvement work in NICUs across the United States, mandated reporting of HAIs (which has been implemented in several states) may be influencing HAI rates. A study examining the impact of these mandates found that CLABSI rates decreased in infants weighing less than 750 g in states with mandated reporting but revealed no impact on overall NICU CLABSI rates (Zachariah et al., 2014). VAP rates also decreased from 1.6 to 0.6 per 1000 ventilator days from 2007 to 2012 (see Fig. 40.1) (Patrick et al., 2014). While catheter-associated UTIs are not very frequent in the NICU, non-catheter-associated UTIs remain a common cause of infections and need for antibiotic treatment in the NICU (Shaikh et al., 2008). SSTIs, on the other hand, appear to be on an increasing trend in both inpatient and emergency settings, likely because of the increasing prevalence in both healthcare and community settings of MRSA, the most common etiologic agent of SSTIs (Hester et al., 2015).

The International Nosocomial Infection Control Consortium published surveillance data from 2007 to 2012 from 503 NICUs in Africa, Asia, Europe, and Latin America (Rosenthal et al., 2014). On examination of the available NICU data, it was concluded that the rates of CLABSI and VAP were generally higher than the corresponding CDC NHSN rates in the United States (Table 40.1;

TABLE 40.1

Health Care–Associated Infection Rates in the United States and Internationally

| CLABSI RATES FOR LEVEL III NICUS IN THE UNITED STATES, 2012 (CDC NHSN) | | | | | |
|--|-------------------------------|------------------|-------------------|-------------------------|--------------------------------------|
| Birthweight Category (g) | No. of Locations ^b | No. of CLABSIs | Central Line Days | Pooled Mean CLABSI Rate | |
| ≤750 | 380 (334) | 420 | 185,851 | 2.3 | |
| 751–1000 | 401 (339) | 256 | 160,230 | 1.6 | |

Rosenthal et al., 2014). Recent advances in resources, technology, and regulations in health care in many countries have led to reductions in infection rates, which are reflected in the reductions in NICU CLABSI and VAP rates seen in the later years of surveillance (Table 40.1; Rosenthal et al., 2014).

Risk Factors for Development of Health Care–Associated Infection

Minimizing exposure to known risk factors for infection is important to reduce the rate of HAIs in the nursery. Experience in the past decade in the NICU has demonstrated that many HAIs previously thought to be not preventable can in fact be substantially decreased in frequency with appropriate preventive interventions.

Risk Factors Related to Patient Characteristics

The risk of developing an HAI is inversely related to gestational age and birthweight (Gaynes et al., 1996; Stoll et al., 1996; Suara et al., 2000; Stover et al., 2001; Stoll et al., 2002; Patrick et al., 2014). Infants with birthweights less than 1000 g have been shown to experience twice the rate of nosocomial bloodstream infections than infants with birthweights greater than 1000 g (Gaynes et al., 1996; Brodie et al., 2000; Stover et al., 2001; Stoll et al., 2002; Geffers et al., 2008). This increased risk to premature infants continues to persist, as demonstrated by an analysis of CDC NHSN data from 2007 to 2012 showing that VLBW infants have a twofold increased risk of developing CLABSI and a 3.5-fold increased risk of VAP compared with normal-weight infants (Patrick et al., 2014). VAPs are more common in infants with underlying cardiopulmonary disease such as bronchopulmonary dysplasia (BPD), as well as infants who have experienced previous thoracoabdominal surgery. UTIs are more prevalent in ex-preterm infants; neonatal males are at higher risk than neonatal females, as are infants with underlying renal anomalies (Shaikh et al., 2008; Foglia and Lorch, 2012). Overall, VLBW infants are more vulnerable to infection, because of both the immaturity of their immune response and their greater need for invasive devices. Additionally, severity of illness scores may serve as an important proxy for physiologic instability and the need for intervention and invasive therapies (Goldmann, 1989; Gray et al., 1995). Infants with an underlying GI condition such as necrotizing enterocolitis, gastroschisis, or omphalocele may be predisposed to mucosal barrier injury and at heightened risk of CLABSI. In a multicenter cohort study in 14 NICUs, 40% of infants who developed CLABSIs had underlying GI conditions associated with loss of mucosal integrity or impaired gut motility or both (Coffin et al., 2014). However, the proportion caused by “enteric pathogens” was not different in the overall group, except for infants with intestinal failure who developed multiple CLABSIs; this latter group experienced higher rates of infections with enteric pathogens (Coffin et al., 2014). A study from the NICHD NRN also demonstrated that VLBW infants with intestinal failure were at increased risk of recurrent bloodstream infections; however, gram-positive organisms were the most frequently implicated pathogens (Cole et al., 2012).

Risk Factors Caused by Necessary Medical Interventions

The use of any type of invasive device increases the risk of infection. The most common invasive devices used in the nursery are intravascular catheters, mechanical ventilators, ventriculoperitoneal shunts, and urinary catheters. In general, risk rises as the duration of exposure lengthens. Compared with adult patients, neonates are at higher risk of CLABSI and at lower risk of VAP and UTI

(Langley et al., 2001; Dudeck et al., 2013). These patterns correlate with the frequency with which these invasive devices are used in the neonatal population.

Prolonged duration of mechanical ventilation is the primary risk factor for development of hospital-acquired pneumonia. Endotracheal tubes circumvent normal airway protective and clearance mechanisms and become coated with biofilms of bacteria, which have the potential to enter the lower airways and cause infections (Garland, 2010). Contamination of respiratory equipment, especially with gram-negative organisms that thrive in moist environments, such as *Acinetobacter*, *Pseudomonas*, and *Flavobacterium* species (spp.), frequently leads to colonization of the respiratory tract (Sole et al., 2002). Aspiration of gastric and oropharyngeal secretions around uncuffed endotracheal tubes could be a mechanism for VAP (Goodwin et al., 1985; Farhath et al., 2008; Garland, 2010). The various closed-system suctioning devices may decrease the risk of environmental contamination during suctioning; however, there is a theoretical risk that they could reintroduce pathogens suctioned from the secretions from major airways into smaller lower airways. While there is a paucity of NICU evidence on the subject, adult studies have demonstrated higher colonization rates but lower VAP rates with closed suctioning systems (Deppe et al., 1990; Johnson et al., 1994; Combes et al., 2000; Cordero et al., 2000; Woodgate and Flenady, 2001; Tablan et al., 2004). Supine positioning and dependent position of the endotracheal tube in relation to the ventilator circuit may increase the risk of VAP by increasing the risk of aspiration (Torres et al., 1992; Drakulovic et al., 1999; Aly et al., 2008). Data on nasal continuous positive airway pressure suggest that its lack of disruption of normal airway protective mechanisms compared with endotracheal tubes may be responsible for lower rates of nosocomial pneumonia; however, the association of nasal continuous positive airway pressure with greater rates of gram-negative sepsis needs further elucidation (Hentschel et al., 2005; Graham et al., 2006).

The intravascular devices commonly used in the neonatal population are peripheral intravenous catheters (PIVCs), umbilical catheters, peripherally inserted central catheters (PICCs), surgically placed central venous catheters (CVCs), and percutaneous arterial catheters. Regardless of the type of device used, the rate of CLABSI appears to be related to the number of days the catheter is in place (Gaynes et al., 1996; Suara et al., 2000; Mahieu et al., 2001; Stoll et al., 2002). Table 40.2 summarizes evidence regarding several of the interventions associated with increased CLABSI risk (Cantey and Milstone, 2015).

PIVCs are the most commonly used device for vascular access in neonates. In adults, the removal of such catheters after 72 hours is recommended. Data in neonates are insufficient to recommend elective removal of PIVCs after 72 hours, because studies have not shown a clear correlation between the higher colonization rate noted after 72 hours and an increased CLABSI rate (Pearson, 1996; Oishi, 2001). However, risks of PIVC infiltration and associated complications, as well as the likely duration of intravenous (IV) access and physiologic disruption often associated with IV insertion, need to be carefully evaluated by clinicians while making decisions around PIVC use and retention.

Data comparing the infection rates of the various types of intravascular catheters are limited. A 2015 Cochrane review of trials comparing PICC lines with PIVCs found that use of a PICC line decreases the risk of complications associated with PIVCs, without increasing the rate of infection (Ainsworth and McGuire, 2015). For central lines, theoretically the risk should be lower for tunneled catheters, because the Dacron cuff proximal to the exit site of a

surgically placed catheter can inhibit the migration of organisms into the catheter tract (Mermel et al., 2001). Adult data suggest that tunneled catheters have lower infection rates than nontunneled catheters; however, studies of neonates requiring tunneled lines show rates of infection comparable with or worse than the reported rates of PICC line infections in other NICU populations (Klein et al., 2003; Freeman et al., 2015). Another recent study from the Netherlands found that umbilical catheters confer the greatest risk of CLABSI (Yumani et al., 2013). This finding is in contrast to the findings of previous studies that found no differences in rates from PICC lines and yet others that found a higher risk with PICC lines (Mahieu et al., 2001; Chien et al., 2002; de Brito et al., 2010; Sannoh et al., 2010). Findings regarding catheter dwell time on CLABSI rates are also mixed. Some studies have found no relationship between catheter dwell time and CLABSI

risk (Mahieu et al., 2001; Smith et al., 2008). However, several others have suggested that increasing risk of CLABSI is associated with PICC and umbilical lines with increased dwell time (Sengupta et al., 2010; Yumani et al., 2013). Recently, a large retrospective review of more than 13,000 infants found that while dwell time did not affect CLABSI risk for PICCs, it did impact CLABSI risk with tunneled catheters, with increased CLABSI risk beyond week 7 from placement (Greenberg et al., 2015). There continues to be much work to be done to determine the ideal IV access and ideal catheter maintenance procedures for the different populations cared for in the NICU.

Exposure to parenteral nutrition has been shown to be associated with increased risk of bloodstream infections, which may in part be mediated by increased use of central lines for delivery of parenteral nutrition (Johnson-Robbins et al., 1996; Padula et al., 2014). Lipid emulsions may decrease the flow rate through the IV catheter, potentiate growth and proliferation of some microorganisms, and interfere with host defense mechanisms by impairing the function of neutrophils and reticuloendothelial cells (Nugent, 1984; Freeman et al., 1990; Langevin et al., 1999). Use of lipid emulsions was independently predictive for the development of CoNS bacteremia (Freeman et al., 1990). Administration of such emulsions has also been linked to a higher risk of HAI with *Candida* and *Malassezia* spp. in neonates (Long and Keyserling, 1985; Redline et al., 1985; Saiman et al., 2000). A recent metaanalysis of predictive factors for neonatal HAIs identified parenteral nutrition and lipid infusions as independent predictors of bloodstream infections (Verstraete et al., 2015).

Histamine-blocking agents, proton pump inhibitors, and postnatally administered corticosteroids are the medications most commonly associated with an increased risk of HAIs among newborns (Graham et al., 2006; Smith et al., 2010; Verstraete et al., 2015). It is hypothesized that the reduced gastric pH associated with the use of histamine-blocking agents promotes bacterial overgrowth and invasion of pathogenic bacteria (Beck-Sague et al., 1994). With greater understanding of the adverse neurodevelopmental consequences of prolonged ventilator need and consequent BPD, there is renewed interest in judicious use of lower-dose steroids after the first 2 weeks postnatally, especially in infants at high risk of developing BPD (Schmidt et al., 2003; Doyle et al., 2005, 2006, 2007; Ambalavanan et al., 2012; Schmidt et al., 2015). However, steroid use has been associated with an increased risk of infection in VLBW infants (Yeh et al., 1997; Stoll et al., 1999), and therefore neonatologists will need to include this concern in any risk–benefit analysis of the use of steroids in their patients.

Risk Factors Associated With the Neonatal Intensive Care Unit and Hospital Environment

Nursery design and staffing influence the risk of infection. Overcrowding and larger workloads decrease compliance with hand washing and raise the risk of HAI (Fridkin et al., 1996; Archibald et al., 1997; Harbarth et al., 1999; Vicca, 1999; Robert et al., 2000). Inadequate numbers of staff and the use of temporary or inexperienced staff members both adversely affect the rate of infection. Studies have shown a relationship between nurse-to-patient ratio and colonization of patients with MRSA and CLABSI rates (Fridkin et al., 1996; Vicca, 1999). Furthermore, strategic nursery design and improvement in nursing staffing correlate with lower rates of HAIs (Gladstone et al., 1990). However, there continue to be nurse staffing challenges, as exemplified by a VON study that identified rates of understaffing and infections in NICUs across the United States (Rogowski et al., 2013).

Many of these HAI risk factors hold true globally. Nosocomial infection rates are much higher in lower-income countries than middle-income and higher-income countries (37.0 vs 11.9 [$P < .02$] vs 17.6 [$P < .05$] CLABSI per 1000 catheter days respectively; Table 40.2), likely reflecting a combination of personnel and resource limitations, overcrowding, lack of infection control regulatory and auditing mechanisms, hospital accreditation, and healthcare workers inexperienced in infection prevention standard practices (Rosenthal et al., 2014).

Health Care–Associated Infection: Distribution by Pathogen

The predominant pathogens responsible for nosocomial bloodstream infections have changed over time. Goldmann (1989) proposed that these trends are explained by changes in the neonatal intensive care patient population and advancing technology. *S. aureus* was the most common nosocomial pathogen in the 1950s and 1960s. In the 1960s and 1970s, gram-negative organisms emerged as the predominant pathogens; globally, these organisms are the most important pathogens responsible for HAIs in the nursery (Stoll et al., 2001). In the United States, CoNS was the most common nosocomial pathogen in the 1990s and early years of the first decade of this century (Gaynes et al., 1996; Stoll et al., 2002). Among the cohort of VLBW infants born between 2002 and 2008 with late-onset infections, the NICHD reported that in singleton infants, gram-positive organisms were responsible for 77% of cases, gram-negative organisms were responsible for 16%, and fungi were responsible for 8% of cases (Table 40.3; Boghossian et al., 2013). These findings are similar to those of studies from the previous decade, suggesting that pathogen distributions have stayed the same in recent times, with CoNS being the most frequent causative pathogen (Stoll et al., 2002; Garland et al., 2008); however, reports from at least one center have noted dramatic declines in CoNS as causative pathogens following the introduction of standardized central line insertion and maintenance bundles and checklists (Bizzarro et al., 2015).

Microbial Resistance

For the clinician, understanding the specific colonization and resistance patterns in the individual NICU is critical. There is clear evidence that antimicrobial resistance is increasing across NICUs. Drug-resistant gram-negative pathogens, in particular, are associated with the highest attributable mortality rates (Makhoul et al., 2005; Shah et al., 2015; Tsai et al., 2016). Cantey and Milstone (2015) identified a marked increase in the number of NICU publications associated with MRSA, vancomycin-resistant enterococcus (VRE), extended-spectrum β -lactamase and carbapenemase producing organisms between 1993 and 2013. NHSN data show that MRSA infection rates tripled in NICUs between 1995 and 2004 (Lessa et al., 2009). Resistant bacteria have been implicated in more than 15% of NICU outbreaks worldwide (Cantey and Milstone, 2015). Colonization with resistant bacteria has been associated with approximately a 33% infection risk with the same pathogen (Singh et al., 2002; Carey et al., 2010; Smith et al., 2010). Many NICUs have adopted periodic surveillance strategies to detect resistant bacteria such as MRSA or VRE (Macnow et al., 2013).

Gram-Positive Bacteria

Coagulase-Negative Staphylococci

CoNS (such as *S. epidermidis*, *S. capitis*, *S. hominis*, *S. warneri*, and *S. haemolyticus*), while commonly thought of as skin

^aThere is a significant difference in the rate between singletons and multiples ($P < .05$). Data from Boghossian NS, Page GP, Bell EF, et al. Late-onset sepsis in very low birth weight infants from singleton and multiple-gestation births. *J Pediatr*. 2013;162:1120–1124.

commensals, are the most common endemic nosocomial pathogen in neonates (Gray et al., 1995; Brodie et al., 2000; Stoll et al., 2002; Garland et al., 2008; Boghossian et al., 2013). Most CoNS infections are bloodstream infections, with a reported incidence of 51%–78% among VLBW infants (Gray et al., 1995; Isaacs et al., 1996; Stoll et al., 1996, 2002; Boghossian et al., 2013). CoNS are lower-virulence pathogens, with low mortality rates noted (Bizzarro et al., 2015). Known risk factors for CoNS infection are low birth weight, lower gestational age, use of CVCs, prolonged parenteral nutrition, use of IV lipid emulsions, postnatal administration of corticosteroids, and prolonged hospital stay (Freeman et al., 1990; Goldmann, 1989; Johnson-Robbins et al., 1996; Brodie et al., 2000). CoNS produce a capsular polysaccharide adhesin—poly(*N*-succinyl glucosamine)—which forms a “biofilm,” enhancing its ability to adhere to intravascular devices (Otto, 2004). Although some studies suggest that prophylactic use of vancomycin or vancomycin locks reduces the risk of CoNS catheter-related infections, this practice is not recommended because of the serious risk of encouraging antibiotic-resistant organisms, especially VRE and staphylococci (Garland et al., 2005).

Staphylococcus aureus

S. aureus has caused epidemics of SSTIs in well baby nurseries and in NICUs and causes up to 10% of CLABSI (Huang et al., 2012; Shane et al., 2012; Filleron et al., 2013; Sanchini et al., 2013; Lee et al., 2014; Blanchard et al., 2015). The skin, nares, and umbilicus

are the most common sites of colonization. MRSA rates differ greatly between institutions but can account for 50%–55% of staphylococcal infections (Lessa et al., 2009; Dolapo et al., 2014; Shane et al., 2012). MRSA colonization increases the risk of MRSA infection (Huang et al., 2006). Consequently, when one is covering for a possible *S. aureus* infection, it is critical to select an antibiotic that is effective against methicillin-resistant strains. Attributable mortality due to *S. aureus* HAI is between 5% and 18%, with rates as high as 25% in VLBW infants, irrespective of whether the strain is methicillin resistant or not (Cohen-Wolkowicz et al., 2007; Shane et al., 2012; Dolapo et al., 2014). *S. aureus* HAI has been found to be associated with increased rates of adverse neurodevelopmental outcomes (Cohen-Wolkowicz et al., 2007).

Enterococcus

Enterococci (*Enterococcus faecalis*, *Enterococcus faecium*) are responsible for both endemic and epidemic HAIs in the NICU and are responsible for approximately 3% of NICU bloodstream infections (Stoll et al., 2002; Boghossian et al., 2013). Use of CVCs, prolonged hospital stay, and prior antibiotic use are recognized risk factors for colonization with these organisms. The GI tract is often the primary source of infection; however, the pathogens are typically spread via the hands of healthcare workers or through environmental contamination. The widespread use of antibiotics has led to the emergence of VRE (Mascini et al., 2005). There are published guidelines to prevent the spread of VRE, which include hand washing, isolation, barrier precautions, and cohorting of infected patients (Gross and Pujat, 2001). Educational programs to limit the indiscriminate use of antibiotics have been effective in decreasing the spread of VRE (Goldmann, 1989; Isaacs, 2000).

Group B Streptococcus

Group B streptococcus remains an important cause of early-onset and late-onset infection in neonates, but neither has a clear role as an HAI.

Gram-Negative Bacteria

Gram-negative organisms are a particularly important cause of nosocomial bloodstream infections, pneumonia, and meningitis because they generally cause severe disease. *Escherichia coli* is the most common gram-negative pathogen (Boghossian et al., 2013). Other gram-negative organisms responsible for HAI include *Klebsiella*, *Pseudomonas*, *Enterobacter*, *Acinetobacter*, *Serratia*, *Haemophilus*, *Citrobacter*, and *Salmonella* spp. (Table 40.3; Boghossian et al., 2013). Gram-negative infections are currently responsible for approximately 15% of infections in the NICU (Boghossian et al., 2013). The GI tract is thought to serve as the reservoir for these bacteria, and prolonged antibiotic therapy may promote selection of these bacteria (Graham et al., 2007; Smith et al., 2010). The attributable mortality is much higher for gram-negative infections than for gram-positive infections (Makhoul et al., 2005; Shah et al., 2015; Tsai et al., 2016). The occurrence of a gram-negative infection in an NICU patient has been found to be associated with a 3.5-fold higher risk of death (Stoll et al., 2002). *Pseudomonas* spp. appear to be particularly virulent, causing death in 42%–75% of infected neonates (Leigh et al., 1995; Karlowicz et al., 2000; Stoll et al., 2002; Tsai et al., 2016).

Fungi

Fungal infections are discussed in detail in Chapter 41. Invasive fungal infection is estimated to occur in 1%–4% of VLBW infants and up to 10% of extremely low birth weight (ELBW) infants,

with the highest risk in infants weighing less than 750 g (Makhoul et al., 2002; Benjamin et al., 2006; Clerihew et al., 2006; Fridkin et al., 2006; Bartels et al., 2007; Benjamin et al., 2010). The rates and predominant fungal species differ considerably between centers. The smallest and most premature infants appear to be at the highest risk, particularly when they are exposed to broad-spectrum antibiotics and long courses of antibiotics. Other identified risk factors are prolonged mechanical ventilation, prolonged use of CVCs, use of lipid emulsions, antenatal antibiotics, and the use of histamine H₂-receptor antagonists (Saiman et al., 2000; Makhoul et al., 2002; Benjamin et al., 2010). Prophylactic fluconazole therapy has shown promise in reducing the rates of colonization and infection with candida; the impact appears greatest in NICUs with high rates of candida infection (Kaufman et al., 2001; Bertini et al., 2005; Dutta et al., 2005; Healy et al., 2005; Aghai et al., 2006; Manzoni et al., 2006; Uko et al., 2006; Manzoni et al., 2007). However, a large randomized controlled trial of prophylactic fluconazole did not show reductions in mortality or the incidence of invasive fungal disease (Benjamin et al., 2014). Although no study has found an increase in the incidence of fluconazole-resistant fungus, resistance remains a concern with any prophylactic strategy. Limiting a prophylactic strategy to NICUs with high rates of invasive candidal disease and to patients with the highest risk will likely provide the greatest benefit with the lowest risk.

Viruses

Viral organisms that commonly cause HAI in the NICU include respiratory syncytial virus (RSV), rhinovirus, metapneumovirus, influenza virus, rotavirus, and enterovirus. Isolated infections generally result from contact with infected caregivers or family members. Nursery epidemics may occur in addition to isolated individual cases. Viral infections have only recently gained attention as causes of HAI and adverse outcomes, in part because of recent advances in the ability to diagnose viral infections. An analysis of infectious outbreaks in NICUs globally found that approximately 10% of outbreaks affecting neonates were attributed to viral causes, with the most common etiologic agents being rotavirus, RSV, enterovirus, hepatitis A virus, and adenovirus (Civardi et al., 2013). Measures to prevent and contain viral infections include standard precautions such as isolation and cohorting of affected patients, meticulous hand hygiene and use of personal protective equipment, and surveillance of patients and healthcare personnel during outbreaks. Alarming, mortality rates for viral outbreaks appear to be similar to those for bacterial outbreaks (7.2% vs 6.4%) (Civardi et al., 2013).

Respiratory Syncytial Virus

RSV is a fastidious organism capable of surviving on inanimate objects for prolonged periods and which can cause severe disease in neonates, particularly those who are premature or who have cardiopulmonary disease. Rapid testing to detect RSV in nasal washings facilitates efforts to cohort infected patients (Madge et al., 1992). The most recent guidelines from the American Academy of Pediatrics (AAP) recommend that all high-risk infants born at less than 29 weeks' gestation, or with chronic lung disease, or with hemodynamically significant congenital heart disease receive up to five doses of palivizumab (an RSV monoclonal antibody) during the RSV season but starting only at hospital discharge (American Academy of Pediatrics et al., 2014). Although current guidelines do not list prophylactic palivizumab for prevention of nosocomial transmission of RSV, some centers choose to provide RSV prophylaxis to at-risk inpatient neonates because of sporadic occurrences

of inpatient nosocomial deaths from RSV (Abadesso et al., 2004; Kurz et al., 2008; Katz and Sullivan, 2009; Berger et al., 2010; Ohler et al., 2013).

Influenza

Influenza is spread primarily via airborne transmission. Hand washing and immunization of healthcare workers are the primary tools to prevent nosocomial spread (Nichol and Hauge, 1997). Some states and institutions mandate yearly immunization among healthcare workers. Infection control guidelines recommend that every healthcare worker wear a mask during contact with infected patients (Nichol and Hauge, 1997). At-risk infants should receive the influenza vaccine during the winter months once they reach the age of 6 months (Committee on Infectious Diseases, 2015). Parents and other close contacts of at-risk infants should also receive influenza vaccination. Oseltamivir is approved by the Food and Drug Administration for treatment (within the first 48 hours of symptoms) of patients older than 2 weeks infected with influenza A virus or influenza B virus; the AAP and CDC recommend its use for treatment of infected infants of any age (Committee on Infectious Diseases, 2015). While safety and efficacy of oseltamivir prophylaxis have not been established in infants younger than 1 year, the CDC recommends its use for this purpose from 3 months of age onward (Committee on Infectious Diseases, 2015). Guidelines for minimizing risk to infants born to mothers who are actively infected have been provided by the CDC (Williams et al., 2013). Pregnant women should receive treatment as soon as possible (Williams et al., 2013). If tolerated, the mother should wear a mask during labor and delivery. After delivery, the newborn should be cared for away from the mother until she has received treatment for 48 hours, has become afebrile, and is able to control cough and secretions (Committee on Infectious Diseases, 2015). If desired, lactation should be facilitated, because the breast milk itself is not thought to be a means of viral transmission (Williams et al., 2013).

Rotavirus

Although rare, epidemics of rotavirus diarrhea may occur in the nursery (Widdowson et al., 2000; Jain et al., 2001; Lee et al., 2001; Herruzo et al., 2009); they are primarily caused by inadequate hand washing and cross-contamination between patients (Bruijning-Verhagen et al., 2012). Standard and contact precautions should be followed throughout the duration of the illness. Some patients have prolonged fecal shedding of low concentrations of the virus; therefore some infection control experts recommend contact precautions for the duration of the hospitalization of such patients. Rotavirus is also an important cause of diarrhea in older infants. Live virus vaccines are now available for the prevention of rotavirus infection. While the 2009 AAP statement recommended administration of the first dose of rotavirus vaccine at discharge from the NICU, several recent studies have documented the safety of pentavalent rotavirus vaccine administration during the hospital stay of preterm infants, with no concern for significant adverse events or symptomatic transmission from shedding (Committee on Infectious Diseases, 2009; Monk et al., 2014; Jaques et al., 2015). Further, one study noted that delaying administration of the first dose until discharge led to more than half of ELBW infants not receiving the rotavirus vaccine, as they missed the window of postnatal age for vaccine administration (Stumpf et al., 2013).

Enterovirus

There are numerous serotypes of enteroviruses, including polioviruses, Coxsackie viruses A and B, echovirus, and nonassigned

subtypes (Chambon et al., 1999). Enterovirus infections have been described among neonates in the well baby nursery and the NICU setting (Isaacs et al., 1989; Wreghitt et al., 1989; Chambon et al., 1999; Sizun et al., 2000; Takami et al., 2000). Both isolated cases and epidemics can occur. The clinical presentation associated with enteroviral infection is variable, ranging from asymptomatic to overwhelming multisystem organ dysfunction with poor prognosis (Isaacs et al., 1989; Wreghitt et al., 1989; Abzug et al., 1993; Keyserling, 1997; Jankovic et al., 1999). The severity of the disease and the likelihood of death are often more pronounced in perinatally acquired cases than in nosocomially acquired cases, presumably related to the lack of maternal antibody present in the neonate (Modlin et al., 1981; Isaacs et al., 1989). Blood and cerebrospinal fluid cultures should be obtained from any patient with clinical symptoms of disease. Polymerase chain reaction analysis is helpful in making a rapid diagnosis (Nigrovic, 2001; Tebruegge and Curtis, 2009). No antiviral agents are currently available to treat enteroviral infections in newborns (Nigrovic, 2001). Although commercially available intravenous immunoglobulin (IVIG) preparations have high levels of neutralizing antibodies to common enterovirus serotypes, there is no clear evidence that administration of immunoglobulin alters the process or outcome of enteroviral infection (Dagan et al., 1983; Abzug et al., 1993; Keyserling, 1997; Tebruegge et al., 2009).

Adverse Outcomes Related to Health Care–Associated Infection

HAIs are a potentially highly modifiable contributor to a spectrum of adverse outcomes, across all gestational and postnatal ages, but especially in the most immature infants (Table 40.4). Studies from the NICHD NRN have demonstrated a striking increase in mortality in VLBW infants who experience late-onset infection (18% in infected infants vs 7% in uninfected infants), with even higher mortality rates for gram-negative or fungal sepsis (Stoll et al., 2002). Several studies have found the length of stay to increase because of sepsis: NICHD NRN data indicated that the mean length of stay increased from 60 to 79 days in VLBW infants, while the VON group found an increase in the length of stay of 4–7 days (Pessoa-Silva et al., 2001; Stoll et al., 2002; Payne et al., 2004). In the subset of infants with intestinal failure due to necrotizing enterocolitis, hospital length of stay and the duration of parenteral nutrition were greatly increased by the occurrence of infections (Cole et al., 2012). A study of VAP in pediatric intensive care units and NICU populations noted an increased duration of mechanical ventilation (by 3 days) (Foglia et al., 2007). There is also strong evidence that infections in VLBW infants are associated with an increased risk of adverse neurodevelopmental outcomes. One early study of more than 6000 ELBW infants found that infants who experienced infection had impaired head growth as well as a significantly increased risk of cerebral palsy, lower Bayley mental and psychomotor development indices, and visual deficits (Stoll et al., 2004a). A secondary analysis of the Trial of Indomethacin Prophylaxis in Preterms (944 ELBW infants) also confirmed that infection was an independent risk factor for neurodevelopmental impairment (Bassler et al., 2009). Most recently, an analysis by the NICHD NRN of trends from 2005 to 2012 noted a decrease in infections across all VLBW gestational ages in this time period, while also noting slight improvements in survival without major morbidity in infants born at 25–28 weeks' gestation; the authors suggest that at least some of this improvement

TABLE 40.4 Adverse Outcomes Associated With Bloodstream Infections in Very Low Birth Weight Infants in the Neonatal Intensive Care Unit

| Adverse Outcome | Study | Adjusted Effect |
|---------------------------------|--------------------------|--|
| Death | Stoll et al. (1996) | 2.4-fold increase (17% vs 7%) |
| | Stoll et al. (2002) | 2.6-fold increase (18% vs 7%) |
| | Makhoul et al. (2002) | 2.0-fold increase (17% vs 9%) |
| Poor neurodevelopmental outcome | De Haan et al. (2013) | OR 4.8 (1.5–15.9) (gram-negative BSI) ^a |
| | Mitha et al. (2013) | OR 2.2 (1.5–3.1) ^b |
| | Schlapbach et al. (2011) | OR 3.2 (1.2–8.5) ^b |
| | Stoll et al. (2004a) | OR 1.4 (1.3–2.2) ^a |
| Increased length of stay | Stoll et al. (1996) | 19–22-day mean increase |
| | Stoll et al. (2002) | 18.6-day mean increase |
| | Makhoul et al. (2002) | 27-day mean increase |
| | Atif (2008) | 9.2-day mean increase |
| Increased cost | Payne et al. (2004) | \$54,539 mean increase |
| | Donovan et al. (2013) | \$16,800 mean increase |

Data from all studies have been adjusted for gestational age.
^aBayley-II motor or cognitive score less than 85, blindness, deafness, or cerebral palsy.
^bCerebral palsy.

 Data from Cantey JB, Milstone AM. Bloodstream infections: epidemiology and resistance. *Clin Perinatol*. 2015;42:1–16.

may plausibly be related to the reduction in infection rates over the same period (Stoll et al., 2015).

Evidence regarding the adverse effects of excess antibiotic exposure continues to mount. Development of antibiotic resistance is a well-known concern, potentially facilitating the emergence and spread of resistant nosocomial pathogens within the NICU (Singh et al., 2002; Millar et al., 2008; Russell et al., 2012; Gibson et al., 2015). In addition, several recent investigations into the impact of gut microbial alterations in early life have suggested associations between early antibiotic exposure, gut microbial dysbiosis, and the occurrence of GI dysfunction, necrotizing enterocolitis, and sepsis, as well as long-term immune dysregulation and GI disorders (Cotten et al., 2009; Kuppala et al., 2011; Sherman et al., 2015; Vangay et al., 2015).

HAIs are also associated with significantly increased use of healthcare resources and healthcare costs (Tambyah et al., 2002; Payne et al., 2004; Kennedy et al., 2013; Zimlichman et al., 2013). One metaanalysis of the costs of HAIs in the United States estimated costs attributable to CLABSI at \$45,814 (95% CI \$30,919–\$65,245), to VAP at \$40,144 (95% CI \$36,286–\$44,220), to surgical site infections at \$20,785 (95% CI \$18,902–\$22,667), and to catheter-associated UTIs at \$896 (95% CI \$603–\$1189)

• BOX 40.2 Principles for the Prevention of Health Care–Acquired Infection in the Neonatal Intensive Care Unit

Observe recommendations for standard precautions with all patient contact.
 Observe recommendations for transmission-based precautions (gowns, gloves, masks, isolation, as indicated).
 Use good nursery design and engineering.
 Appropriate nurse-to-patient ratio
 Avoidance of overcrowding and excessive workload
 Improve hand hygiene compliance (Box 40.3).
 Minimize risk of contamination of central lines—adopt care bundles.
 Provide meticulous skin care.
 Encourage early and appropriate advancement of enteral feedings.
 Perform continuous monitoring and surveillance of health care–acquired infection rates in the neonatal intensive care unit.
 Provide education and feedback to nursery personnel.

(Zimlichman et al., 2013). A retrospective study of HAIs in NICUs calculated an incremental cost of \$16,800 attributable to bloodstream infections (Donovan et al., 2013), whereas another study in VLBW infants found a more modest cost increase but still amounting to thousands of dollars (\$1280–\$5875 per infection) (Payne et al., 2004). Attributable costs in a study of pediatric and neonatal VAP were estimated at \$30,000 (Foglia et al., 2007).

Thus decreasing HAI rates in the NICU can reduce the risk of adverse events in infants during their hospital stay, thereby decreasing the incidence of short-term and long-term adverse outcomes, length of stay, and direct healthcare costs. HAIs have therefore become a very important focus of quality improvement efforts in NICUs across the United States and the world.

Prevention of Health Care–Associated Infection

Overall Approach to Infection Control

The CDC recommends a two-tiered approach to infection control (Box 40.2). Standard precautions should be used with all patient contact regardless of the underlying diagnosis or infectious status. These precautions consist of universal precautions (designed to prevent blood and body fluid contamination) and body substance precautions (designed to prevent contamination with moist substances). Transmission-based precautions are necessary when a patient is infected with a known or suspected pathogen that is associated with a high risk of contamination via airborne or droplet transmission or contact with the skin or contaminated surfaces (Garner, 1996).

Guidelines for Hand Hygiene Practices

Despite knowledge of the importance of hand hygiene since the 1800s, as elucidated by Labarraque and Semmelweis (Boyce and Pittet, 2002), healthcare settings continue to face challenges in establishing optimal hand hygiene practices among caregivers. Good hand hygiene is the cornerstone of HAI reduction efforts (Larson, 1995; Polin et al., 2012a). Hand hygiene techniques are effective in decreasing the colonization rate of resident and transient flora and have been shown to reduce cross-contamination among patients.

• BOX 40.3 World Health Organization Recommendations for Hand Hygiene

- Wash hands with soap and water when they are visibly dirty or soiled or after use of the toilet.
- Use alcohol-based hand rub for routine activities if hands are not soiled; if alcohol-based hand rub is not obtainable, wash hands with soap and water. Brushes are not recommended (even for surgical scrubs).
- Perform hand hygiene:
 - Before and after touching the patient
 - Before handling invasive device, regardless of whether gloves are worn
 - After contact with body fluids, mucous membranes, nonintact skin, dressings
 - If moving from a contaminated body site to another body site on the same patient
 - After contact with inanimate surfaces and objects in the immediate vicinity of the patient
 - After removing sterile or nonsterile gloves
- Selection and handling of hand hygiene agents
 - Provide products with a low irritancy potential.
 - Solicit input regarding skin tolerance, feel, and fragrance of products being considered.
 - Determine known interaction between products used to clean hands, skin care products, and the types of gloves used in the institution.
 - Ensure that dispensers are accessible at the point of care.
 - Provide alternatives for individuals with adverse reactions to standard products.
 - When alcohol-based hand rub is available in the healthcare facility, use of antimicrobial soap is not recommended.
 - Soap and alcohol-based hand rub should not be used concomitantly.
- Use of gloves:
 - The use of gloves does not replace the need for hand hygiene.
 - Wear gloves when it can be reasonably anticipated that contact with blood or other potentially infectious materials, mucous membranes, or nonintact skin will occur.
 - Remove gloves after caring for a patient; do not reuse them with other patients.
 - Change or remove gloves during patient care if moving from a contaminated body site to either another body site within the same patient or the environment.
- Other aspects:
 - Do not wear artificial fingernails or extenders, keep natural nails short
- Hand hygiene promotion programs:
 - Focus specifically on factors with significant influence on behavior and not only on the type of hand hygiene product. The strategy should be multifaceted and multimodal and include education and senior executive support for implementation.
 - Educate staff about the types of patient-care activities that result in hand contamination and about the advantages and disadvantages of various methods used to clean their hands.
 - Monitor adherence to hand hygiene practices, and provide performance feedback.
 - Encourage partnerships between patients, their families, and healthcare workers.

The World Health Organization offers publicly available educational resources to encourage appropriate hand hygiene in healthcare settings and tools for implementation of hand hygiene training and auditing programs: http://www.who.int/gpsc/5may/EN_PSP_GPSC1_5May_2016/en.

Modified from Polin RA, Denson S, Brady MT, Committee on Fetus and Newborn, Committee on Infectious Diseases. Strategies for prevention of health care-associated infections in the NICU. Pediatrics. 2012;129:e1085–e1093.

Direct patient contact and respiratory tract care seem to be particularly associated with contamination (Pittet et al., 1999). Organisms such as RSV, *S. aureus*, and gram-negative bacilli are able to survive on inanimate objects (“fomites”), so holding an infant infected with one of these organisms, changing diapers, and even touching items in the infant’s environment can result in hand contamination (Goldmann, 1989; Boyce and Pittet, 2002).

Recommendations on indications and techniques for hand hygiene were published by the CDC in 2002 and updated by the World Health Organization in 2009 (Box 40.3; Storr et al., 2009). These guidelines will be effective only if every healthcare provider performs hand hygiene before and after every patient contact. Reported barriers to compliance with hand hygiene recommendations include skin irritation, poor accessibility of sinks or cleansing agents, insufficient time, heavy workload, understaffing, and lack of information. A common misconception is that use of gloves obviates the need for adequate hand hygiene. Leakage and contamination of gloves have been reported (Larson, 1995; Boyce and Pittet, 2002). Disposable single-use gloves should be removed after each patient encounter, and hands should be washed before and after their use. The World Health Organization has a number of excellent, publicly available educational resources to encourage appropriate hand hygiene in healthcare settings, including hand hygiene videos in many languages and tools for implementation of hand hygiene training and auditing programs (http://www.who.int/gpsc/5may/EN_PSP_GPSC1_5May_2016/en/).

Hand hygiene is extremely cost-effective. The additional hospital charges associated with a single HAI may almost equal the yearly

hand hygiene budget. One study estimated the cost of a hand hygiene intervention program to be approximately \$57,000 per year (Pittet et al., 2000). Assuming that 25% of the observed decrease in infections was attributable to improved hand hygiene practices, a saving of \$2100 was estimated for every infection averted.

Guidelines for Gloves and Gowns

Although gowning by healthcare workers is still a common practice in many countries, a metaanalysis of studies of gowning in newborn nurseries revealed that gowning by healthcare workers did not reduce rates of colonization, rates of infection, length of stay, or mortality in infants (Webster and Pritchard, 2003). Moreover, an observational study noted that when increasing numbers of patients were placed under contact precautions, necessitating gowning and gloving, this actually led to a decrease in compliance with precautions (Dhar et al., 2014). However, recent studies have shown that use of nonsterile gloves along with correct hand hygiene practices could reduce bloodstream infections in preterm infants compared to hand hygiene alone (Janota et al., 2014; Kaufman et al., 2014).

Recent Quality Improvement Efforts at Reduction of Health Care–Associated Infection in Neonatal Intensive Care Units

In recent years, many NICUs and quality improvement collaboratives have described their success in decreasing the rate of central

line-associated infections (Kaplan et al., 2011; Schulman et al., 2011; Wirtschafter et al., 2011; Payne et al., 2012; Fisher et al., 2013; Lee et al., 2014; Shepherd et al., 2015). Several guiding principles and common themes are present in these success stories. A key and powerful initial step is comparing institutional performance (or “benchmarking”) to improve understanding of the performance of a NICU in comparison with peer institutions and to recognize opportunities for improvement. Monitoring, surveillance, and benchmarking of the HAI rates in the nursery are critical components of any prevention program. There is power in knowing how an individual NICU compares with others, and there is empowerment in knowing that preventing HAIs is possible (Schulman et al., 2009). Next, formation of “quality improvement collaboratives” helps multiple institutions develop common sets of best practices and common definitions and attempts to minimize interhospital variation in outcomes, allowing lesser performing hospitals to learn from hospitals with lower rates of infections. Several statewide and other collaboratives have reported reductions in CLABSI rates with use of this strategy (Kaplan et al., 2011; Schulman et al., 2011; Wirtschafter et al., 2011; Payne et al., 2012; Fisher et al., 2013; Lee et al., 2014; Shepherd et al., 2015; Piazza et al., 2016). These significant successes have been accomplished with the development and implementation of care “bundles,” incorporating a group of interventions aimed at standardizing care to minimize HAIs.

Prevention of Central Line–Associated Bloodstream Infection

The care and maintenance of CVCs are key to reducing CLABSIs. On the basis of knowledge of risk factors, and quality improvement efforts, most institutions currently adopt a “care bundle” of practices surrounding central line insertion and maintenance that have been shown to be effective at reducing CLABSI rates (Box 40.4; Schulman et al., 2009; Kaplan et al., 2011; Wirtschafter et al., 2011; Payne et al., 2012; Fisher et al., 2013; Lee et al., 2014; Shepherd et al., 2015). The key elements during catheter insertion are hand hygiene, aseptic technique, skin antisepsis, and sterile dressing technique. Best practices during catheter maintenance include hand hygiene, daily review of line necessity, daily inspection of the insertion site and dressing, standardization of practices around IV tubing changes, and “scrubbing the hub” of the central line to minimize contamination (Box 40.4). Several NICUs have adopted practices targeting early removal of central lines, when infants advancing on enteral feedings demonstrate tolerance of 70%–80% of goal volume feeds. A recent study from a multicenter collaborative of Children’s Hospital NICUs used an innovative approach, combining orchestrated testing with quality improvement efforts, to pinpoint individual bundle interventions that were likely to have the greatest impact on CLABSI reduction (Piazza et al., 2016). Specific guidelines around use of umbilical catheters have also been developed, emphasizing timely removal—not later than 14 days from placement for umbilical venous catheters and ideally not later than 5 days for umbilical arterial catheters (O’Grady et al., 2011; Polin et al., 2012a).

A metaanalysis comparing skin antiseptic agents found that use of chlorhexidine gluconate for catheter site care reduced the risk of CLABSI by 50% compared with use of solutions containing povidone–iodine (Chaiyakunapruk et al., 2002). However, chlorhexidine is not approved by the Food and Drug Administration for use in infants younger than under 2 months. A randomized trial in VLBW infants showed that while chlorhexidine

• BOX 40.4 Example of Central-Line Insertion and Maintenance Bundle Elements

Insertion Bundle

- Establish a central line kit/cart to consolidate all items necessary for the procedure.
- Perform hand hygiene with a hospital-approved alcohol-based product or antiseptic-containing soap before and after palpating insertion sites or inserting the central line.
- Use maximal barrier precautions (including sterile gown, sterile gloves, surgical mask, hat, and large sterile drape).
- Disinfect skin with appropriate antiseptic (2% chlorhexidine, 70% alcohol) before catheter insertion.
- Use either sterile transparent semipermeable dressing or sterile gauze to cover the insertion site.

Maintenance Bundle

- Perform hand hygiene with a hospital-approved alcohol-based product or antiseptic-containing soap before and after accessing a catheter or changing a dressing.
- Evaluate the catheter insertion site daily for dressing integrity and signs of infection.
- If the dressing is damp/soiled/loose, change the dressing aseptically, and disinfect skin around insertion site with an appropriate antiseptic (2% chlorhexidine, 70% alcohol).
- Develop and use a standardized intravenous tubing setup and changes.
- Maintain an aseptic technique when changing intravenous tubing and when entering the catheter, including “scrub the hub.”
- Daily review of catheter necessity with prompt removal when no longer essential

Modified from Schulman J, Wirtschafter DD, Kurtin P. Neonatal intensive care unit collaboration to decrease hospital-acquired bloodstream infections: from comparative performance reports to improvement networks. Pediatr Clin North Am. 2009;56:865–892.

gluconate-containing dressings reduced colonization of central venous lines (compared with povidone–iodine), CLABSI rates were comparable with the two modes of catheter site care; of note, chlorhexidine was associated with high contact dermatitis rates in the most immature infants (Garland et al., 2001).

There are some data describing the use of prophylactic vancomycin and antibiotic lock therapy with vancomycin in neonates, suggesting a reduction in CoNS bloodstream infection; however, these studies did not demonstrate reductions in length of stay or mortality. Given the concerns for potential development of antibiotic resistance with widespread use of prophylactic antibiotics, these practices are not recommended (Craft et al., 2000; Garland et al., 2002; Taylor et al., 2015). A similar concern regarding the possibility of fluconazole-resistant fungal infections, fluconazole-related toxicity, and lack of evidence regarding mortality or long-term morbidity reduction has limited the recommendation for prophylactic fluconazole to high-risk units, despite evidence of fungal CLABSI reduction with prophylactic fluconazole from randomized trials (Clerihew et al., 2007).

Prevention of Health Care–Associated Pneumonia

Similarly to CLABSI prevention efforts, best practice bundles for VAP prevention have been adopted in many hospitals. The key elements of VAP prevention as recommended by the CDC include surveillance for VAP (which does not include routine cultures), prevention of bacterial transmission, staff education, and risk reduction in the patient (Tablan et al., 2004; Polin et al., 2012a).

Key practices that may help reduce the risk of VAP include timely removal of tracheal tubes from patients, minimizing aspiration of pathogenic bacteria by elevating the head of the bed by 30–45 degrees, and performing oral hygiene (Tablan et al., 2004). There is no clear evidence of the superiority of closed versus open suctioning systems in minimizing VAP risk (Deppe et al., 1990; Woodgate and Flenady, 2001; Tablan et al., 2004).

Other Aspects of Prevention and Management of Health Care–Acquired Infections

Skin Care

The skin of VLBW preterm infants is immature and an ineffective barrier to prevent transepidermal loss of water and invasion of bacteria. The stratum corneum has mechanical and chemical properties that decrease the risk of infection (Darmstadt and Dinulos, 2000) and matures at approximately 32 weeks' gestation. In a prematurely born neonate, the maturation process is accelerated and is usually complete by 2–4 weeks after birth (Darmstadt and Dinulos, 2000). There is no consensus on the most effective skin care practices for VLBW infants (Baker et al., 1999; Munson et al., 1999). While early studies demonstrated that topical application of emollients protected the developing epidermal layer and reduced transepidermal water loss, a metaanalysis showed an increased risk of CoNS infections with topical emollient application (Soll and Edwards, 2000).

Human Milk Feedings

Several studies have demonstrated lower risks of sepsis and necrotizing enterocolitis with early enteral feeding with human milk. The various mechanisms proposed for the beneficial effect of human milk feeding include its content of immunoprotective substances and prebiotics and probiotics that modulate the development of a protective infant gut microbiome. However, a metaanalysis of human milk studies demonstrated a lack of infection protection from human milk feedings (de Silva et al., 2004). Additional studies are required to clarify this question.

Catheter Removal Following Central Line–Associated Bloodstream Infection

A retrospective review compared outcomes in patients in whom catheters were removed at the onset of infection with those in whom catheters remained in place (Benjamin et al., 2001). Forty-six percent of infants in whom in-place catheter sterilization was attempted had complications, compared with 8% of infants whose catheters were removed. Infants with gram-negative infections were more likely to have complications if catheters remained in place (Benjamin et al., 2001). A study of infants with CoNS CLABSI found no difference in complications or mortality rate if catheter removal was delayed (Karlowicz et al., 2000); however, these patients were more likely to have persistently positive culture results when their lines were not removed with the first positive culture result (43% vs 13% for immediate catheter removal). In general, patients with CLABSI due to gram-negative or fungal pathogens should have their catheters removed as early as possible; patients with CLABSI caused by CoNS should undergo catheter removal if the culture results are persistently positive or if the patient's condition is unstable (Karlowicz et al., 2000; Benjamin et al., 2001).

Antibiotic and Adjunctive Therapies

Antibiotic choice should initially cover a broad spectrum of pathogens and should then be narrowed as soon as possible to

cover the specific bacteria identified once sensitivities are known. Antibiotic use should be discontinued if infection is not proved and is not likely. Coverage for *Pseudomonas* spp. or other resistant gram-negative organisms should be considered in patients with rapid clinical deterioration (Karlowicz et al., 2000; Stoll et al., 2002). However, empiric broad-spectrum antibiotic use should be limited as much as possible to avoid development of resistant infections (Dellit et al., 2007).

The most recent metaanalysis update on the prophylactic use of IVIG in preterm neonates included data on immunoglobulin M–enriched IVIG and found no reduction in mortality or adverse neurodevelopmental outcomes (Ohlsson and Lacy, 2015). IVIG is therefore not recommended for routine use in suspected or proven sepsis (Ohlsson and Lacy, 2015). Hemopoietic colony-stimulating factors (granulocyte and granulocyte–macrophage) are effective in raising the neutrophil count but have not consistently decreased HAI rates or mortality (Modi and Carr, 2000; Carr et al., 2003). A metaanalysis of randomized controlled trials of orally administered lactoferrin for prevention of sepsis and necrotizing enterocolitis suggests a decrease in the development of late-onset sepsis (RR 0.49, 95% CI 0.32–0.73) and all-cause mortality (RR 0.30, 95% CI 0.12–0.75) (Pammi and Abrams, 2015); additional data are needed to confirm these benefits. A recent metaanalysis of probiotic trials showed a reduction in the development of late-onset sepsis in preterm infants (RR 0.86, 95% CI 0.74–0.98), contradicting the results of large randomized controlled trials and previous metaanalyses (Garland et al., 2011; AlFaleh and Anabrees, 2014; Lau and Chamberlain, 2015; Costeloe et al., 2016; Rao et al., 2016). Conflicting results may in part be due to variability in probiotic composition between studies (AlFaleh and Anabrees, 2014; Rao et al., 2016).

Conclusion

Interventions to reduce HAI are a cornerstone of excellence in NICU care. While it is encouraging that HAIs in US NICUs have shown trends toward reduction in the last decade, CLABSI and other HAIs continue to cause significant morbidity and death in the most vulnerable NICU patients. Considerable work remains to be done in the United States and across the world to move closer to the ideal goal of zero preventable harm. Collaborative quality improvement approaches, benchmarking, and emphasizing “bundles” of good practices are key to accomplishing these goals. Clinicians must continue to focus on effective prevention strategies, including adherence to strict hand hygiene policies, minimal use of invasive devices, promotion of enteral nutrition, surveillance of infection patterns, and education of all nursery staff members.

Fungal Infections in the Neonatal Intensive Care Unit

MARGARET K. HOSTETTER AND CHRISTINE A. GLEASON

KEY POINTS

- The most important risk factor for fungal infection is gestational age.
- Fungi account for approximately 12% of neonatal late-onset sepsis, with a mortality rate of approximately 32%.
- When a lumbar puncture is performed, 10%–50% of candidemic infants have associated meningitis and a significant percentage of extremely low birth weight (ELBW) infants with *Candida* meningitis have negative blood cultures.
- Any *Candida* species isolated from a blood culture should never be regarded as a contaminant.
- Rapid institution of parenteral amphotericin B deoxycholate is the therapy of choice for systemic fungal infection; if there is also meningitis, 5-flucytosine or fluconazole should be added.
- Central venous catheters should be removed within 24 hours after the identification of yeasts in the blood culture, if possible.
- The finding that prophylactic fluconazole reduces the incidence of invasive neonatal fungal infections should be interpreted with caution; nevertheless, recent guidelines recommend fluconazole prophylaxis in ELBW (<1000 g birthweight) infants in nurseries with high rates (>10%) of invasive candidiasis.

Epidemiology

Invasive fungal infection occurs in approximately 1%–2% of all infants admitted to US neonatal intensive care units (NICU) (Stoll et al., 1996), and the incidence rises dramatically with decreasing gestational age. Among the fungi, *Candida* species (spp.) are the dominant pathogens, with infections about evenly distributed among *C. albicans* and non-*C. albicans* spp. (*C. parapsilosis*, *C. orthopsilosis*/*C. metapsilosis*, *C. glabrata*, *C. guilliermondii*, *C. krusei*, and *C. lusitanae*). *Candida* spp. are the third most common cause of late-onset sepsis in the NICU, with a fatality rate more than sevenfold greater than that of *Staphylococcus epidermidis*, the most common pathogen found in the NICU (Benjamin et al., 2000; Saiman et al., 2001). In late-onset sepsis, fungi account for approximately 12.2% of cases, with a mortality rate of 31.8% (Plano, 2010). Other fungi encountered include *Aspergillus fumigatus* and *A. flavus* and *Malassezia furfur* and *M. pachydermatis*. The yeast *Cryptococcus neoformans* and the fungi *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* are rarely, if ever, seen in the NICU.

The most important risk factor for fungal infection is gestational age. In a survey of 2847 infants from six different nurseries, the incidence of candidemia in infants weighing less than 800 g (7.55%) was 25 times that of the infants weighing more than 1500 g (Fig. 41.1) (Saiman et al., 2000). This latter group acquires bloodborne candidal infection in association with congenital anomalies, especially those of the gastrointestinal tract (Rabalais et al., 1996). Candidemia carries a mortality rate exceeding 25% in most studies (Chapman and Faix, 2000; Weese-Mayer et al., 1987).

Colonization with ubiquitous fungal spp. occurs in at least 25% of very low birth weight (VLBW) infants (Baley et al., 1986), and both the amount of *Candida* in the gastrointestinal tract (Pappu-Katikaneni et al., 1990) and colonization at sites such as endotracheal tubes (Rowen et al., 1994) have been correlated with increased risk of invasive disease caused by *Candida* spp. Prospective studies correlating colonization by other fungal genera (e.g., *Aspergillus*, *Malassezia*) with risk of invasive disease have not been done.

Apart from colonization and gestational age, other host factors that contribute to the susceptibility of the NICU neonate to fungal infection include a 5-minute Apgar score of less than five and an age-dependent immunocompromised state ascribable to reduced numbers of T cells, impaired phagocyte number and function, and reduced levels of complement (Zach and Hostetter, 1989; Maródi et al., 1994; Rebuck et al., 1995; Witek-Janusek et al., 2002). Concomitants of NICU care that are thought to increase the risk of fungal infections include length of stay greater than 1 week, indwelling central venous catheters (CVCs), abdominal surgery, parenteral nutrition, intralipids, H₂ blockers, endotracheal intubation, and prolonged use of broad-spectrum antimicrobials, especially third-generation cephalosporins (Saiman et al., 2000; Saiman et al., 2001; Cotten et al., 2006). Other centers have identified associations with systemic steroids and catecholamine infusions in retrospective studies and with topical petrolatum in a prospective case-control study (Botas et al., 1995; Benjamin et al., 2000; Campbell et al., 2000).

Interestingly, a number of variables appear not to associate with candidal colonization, including use of antibiotics in the mother, premature rupture of the membranes, the infant's gender, use of antimicrobial agents other than third-generation cephalosporins in the infant, surgical procedures, or frequency of intubation (Saiman et al., 2001). Although approximately 5% of NICU staff carry *C. albicans* on the hands and 19% carry *C. parapsilosis*, there is no

• **Fig. 41.1** Incidence of Candidemia Related to Birthweight in Grams. (Data from Saiman L, Ludington E, Pfaller M, et al. Risk factors for candidemia in neonatal intensive care unit patients. The National Epidemiology of Mycosis Survey study group. *Pediatr Infect Dis J.* 2000;19:319–324.)

correlation with site-specific rates of neonate colonization (Saiman et al., 2001).

This chapter will place its major emphasis on infections caused by *Candida* spp. and will also discuss infections caused by other fungi, as well as the approach to diagnosis, treatment, and management of infants with fungal infection.

Infections Caused by *Candida* Species

Congenital Candidiasis

Presenting within the first 24 hours of life in both full-term and premature neonates, congenital candidiasis, a very rare entity, manifests as a deeply erythematous skin rash in the setting of pronounced neutrophilia, with white blood cell counts often rising to 50,000 mm³ or more. *Candida* funisitis (discussed later in the chapter) can be an infrequent accompaniment. In the full-term neonate, there are usually no invasive consequences, and desquamation typically ensues within 2 to 3 days. In contrast, the condition is life-threatening in the premature neonate (Dvorak and Gavaller, 1966; Johnson et al., 1981) and is distinguished by a pustular rash, hazy infiltrates reminiscent of respiratory distress syndrome on chest radiograph, and frequently positive blood cultures. The premature neonate is thought to acquire the organism from inhalation of infected amniotic fluid.

Diagnosis in both premature and full-term neonates requires visualization of the organism on Gram stain from a bullous lesion or an opened pustule. On rare occasions, the placenta has yielded the diagnosis. Treatment for the full-term neonate requires only the full-body application of topical antifungal creams containing either nystatin or azoles such as miconazole or clotrimazole. In the premature neonate, the initiation of parenteral amphotericin B deoxycholate at a dose of 1 to 1.5 mg/kg is mandatory (this dose may be reduced to 1.0 mg/kg), but respiratory involvement typically heralds death despite antifungal therapy. Except where noted, all dosages come from *Nelson's Pediatric Antimicrobial Therapy*, 2017 edition, AAP press.

Local Infections With *Candida* Species

Diaper Dermatitis

This entity presents as an erythematous, erosive dermatitis of the perineal region, typically with pustular “satellite lesions” beyond the borders of the rash. Predisposing factors include systemic

antibiotics, glucosuria, and wet diapers. Care must be taken to differentiate this tractable condition from invasive fungal dermatitis (discussed later in the chapter). The former responds well to topical antifungal ointments.

Funisitis

Infection of the umbilical cord with *Candida* spp., while rare, is an indicator of chorioamnionitis and carries a poor prognosis, especially in the premature neonate (Qureshi et al., 1998). A minority of neonates in one study (16%) had associated congenital candidiasis. Intrauterine contraceptive devices or cervical cerclage was reported in 16% of the mothers.

Urinary Tract Infection

Isolation of *Candida* spp. from a catheterized specimen or via suprapubic bladder aspiration, as opposed to a bagged sample, is a reliable indicator of infection, although asymptomatic colonization of urinary catheters, stents, or nephrostomy tubes can be difficult to distinguish from true infection (Lundstrom and Sobel, 2001).

The presence of candiduria in the NICU neonate is associated with renal candidiasis—the latter manifested by cortical abscesses or fungal mycelia in the collecting system (“fungus balls”)—nearly half the time and may be a cause of frank obstruction (Bryant et al., 1999). Thus in contrast to older children or adults, the finding of candiduria in the NICU neonate should prompt blood cultures and renal imaging at the very least. If blood cultures prove to be positive, a full evaluation for disseminated candidiasis should be undertaken (discussed later in the chapter).

Because of the high prevalence of associated upper tract disease, imaging of the kidneys by ultrasonography should occur upon isolation of the organism from a catheterized urine specimen or from a suprapubic bladder aspiration. Approximately half of patients who eventually develop upper tract manifestations will display them on the first ultrasound (Bryant et al., 1999). Therefore follow-up imaging is recommended both to ensure the clearance of fungal mycelia, if present, and to monitor for later development of this complication. Unfortunately, no standard interval for monitoring has been proposed. However, in the infant who remains persistently funguric or candiduric, a single negative ultrasound should not be considered definitive.

Removal of a colonized urinary catheter may suffice for treatment in a patient without pyuria or systemic symptoms. Disease confined to the lower tract is best addressed with azoles (e.g., fluconazole, 4 to 6 mg/kg per day). Upper tract disease requires parenteral amphotericin B in systemic doses (1 mg/kg per day). Liposomal amphotericin B may not be an acceptable alternative. The particles in at least one liposomal preparation (Abelcet) appear to be too large to penetrate the adult kidney (Agustin et al., 1999), and this author has seen a premature newborn whose persistent candiduria failed to resolve until Abelcet was changed to amphotericin B deoxycholate.

Peritonitis

Candida peritonitis typically develops as a consequence of bowel perforation or, rarely, as a complication of peritoneal dialysis. In the former situation, multiple organisms such as gram-negative rods and enterococci may also be involved, and the neonate is at risk for sepsis with any one of them (Johnson et al., 1980). Peritonitis associated with a peritoneal dialysis catheter usually occurs as an isolated process, and the outcome is much better.

Spontaneous intestinal perforation associated with *Candida* peritonitis with or without sepsis has been described within 7–10

days of birth in neonates weighing less than 1000 g, typically in the absence of necrotizing enterocolitis (Meyer et al., 1991; Mintz and Applebaum, 1993; Adderson et al., 1998; Holland et al., 2003). Hallmarks include bluish discoloration of the abdomen and a gasless pattern on abdominal film. A substantial proportion of these neonates will have systemic candidiasis, although *S. epidermidis* can also be seen. In a small study of seven patients (Holland et al., 2003), deficiency of the muscularis propria was found in six.

Diagnosis requires visualization of the organism on a Gram stain of peritoneal fluid sterily obtained or culture of the organism from the same source. Isolation of *Candida* spp. from the peritoneal fluid should always prompt a search for bowel perforation, either by radiology or by surgical exploration, depending upon the clinical circumstances.

Treatment of *Candida* peritonitis caused by necrotizing enterocolitis or bowel perforation requires surgical evaluation, supportive therapy, and direct address of all contaminating microorganisms in the peritoneal fluid and the bloodstream. The typical regimen should address enterococci, gram-negative rods, and anaerobes together with systemic antifungal therapy, with the most likely choice being amphotericin B. *Candida* spp. isolated from peritoneal dialysate can be treated with removal of the catheter and a short course (7–10 days) of amphotericin B therapy in a dose of 0.3 to 0.5 mg/kg per day. The catheter can typically be reinserted within 24–48 hours, once the Gram stain is free of yeast cells.

Systemic Infection

Candidemia Associated With Central Venous Catheters

The association between prematurity and bloodborne candidal infections has been recognized for 25 years (Baley et al., 1984; Johnson et al., 1984). Over this same period of time, the incidence of candidemia has escalated from 25 to 123 cases per 10,000 NICU admissions (Kossoff et al., 1998; Saiman et al., 2000). The median time of onset is approximately 30 days of age (Baley et al., 1984). In a large multicenter study, colonization of the gastrointestinal tract preceded candidemia in 43% of cases (Saiman et al., 2000).

A variety of nonspecific clinical findings may be associated with this presentation of candidal disease, including respiratory decompensation, feeding intolerance, temperature instability, or mild thrombocytopenia. It is unclear whether the latter manifestation relates more to the use of heparin in intravenous (IV) and peripheral catheters or to the presence of *Candida* spp. in the bloodstream.

Any *Candida* spp. isolated from a blood culture should never be regarded as a contaminant and should prompt an immediate search for evidence of dissemination, which occurs in approximately 10% of premature newborns with candidemia (Patriquin et al., 1980; Noyola et al., 2001). A thorough evaluation includes ophthalmologic examination and ultrasonography of the heart, venous system, and abdomen. When lumbar puncture is performed, 10%–50% of candidemic neonates may have associated meningitis (Faix, 1984; Benjamin et al., 2006); in one prospective study, nearly 50% of ELBW neonates with *Candida* meningitis (13/27) had negative blood cultures (Benjamin et al., 2006).

Numerous studies have shown that CVCs should be removed within 24 hours of identification of yeasts in the blood culture (Karlowicz et al., 2000); in particular, removal of the CVCs within 3 days is associated with a significantly shorter median duration of candidemia (3 days vs 6 days) and a reduced mortality rate (0% vs 39%). In at least one study of candidemia, delayed removal of CVCs was associated with neurodevelopmental impairment at

18–22 months (Benjamin et al., 2006). Many experts recommend routine echocardiograms for patients with catheter-associated candidemia, to look for thrombi before removal of the catheter. However, even with the prompt removal of the catheter and institution of appropriate antifungal therapy, a substantial proportion of infants may exhibit prolonged candidemia lasting 1 to 3 weeks (Chapman and Faix, 2000).

Disseminated Candidiasis

Mortality rates approach 30% for this dreaded complication of candidemia. Once again, *C. albicans* is the leading pathogen. Organ involvement is most common in the vascular tree at catheter sites (15.2%), followed by the kidneys (7.7%) (Patriquin et al., 1980; Noyola et al., 2001). Eye involvement occurs in approximately 6% of infants. Thrombi within the vascular bed may be particularly difficult to eradicate with antifungal therapy; infants with right atrial thrombi may benefit from atriotomy (Foker et al., 1984). Other sites less frequently involved include the liver, spleen, and skeletal system. In infection of the bones and joints in premature newborns, *Candida* spp. are typically the second most likely pathogen, preceded by *S. aureus* (Ho et al., 1989).

Antifungal Therapy for Systemic Infection

As is true of most medications used in the NICU, dosing recommendations for antifungal therapies have not undergone rigorous testing in this patient population. With that caveat in mind, practice guidelines for this difficult clinical problem are suggested. Amphotericin B is the “gold standard” antifungal agent for treatment of systemic neonatal fungal infection. The drug binds to ergosterol in the membrane of fungi, facilitating membrane leakage. Rapid institution of parenteral amphotericin B deoxycholate in doses of 1 mg/kg per day, given by IV infusion over 2–6 hours, is the therapy of choice for systemic infection, including catheter-associated candidemia and disseminated candidiasis. No more than 24 hours should elapse before the infant is receiving a therapeutic dose of 0.7 to 1.0 mg/kg per day. Liposomal amphotericin B in a single dose of 5 mg/kg per day as an IV infusion over 2 hours (Weitkamp et al., 1998; Juster-Reicher et al., 2003) is an equivalent choice for initial therapy, but clinicians should be aware that some lipid formulations (e.g., Abelcet) have decreased renal penetration and are therefore not appropriate choices in disseminated candidiasis with renal infection.

Azoles are fungistatic agents that interfere with ergosterol synthesis by inhibiting C-14 alpha demethylase, a cytochrome P450 enzyme. Some experts recommend this class of antifungals as initial therapy for *C. albicans* infection; because of their fungistatic effects, others use them primarily to complete a course of antifungal therapy after clearance of the infecting organisms. Fluconazole, the most frequently used, requires an IV loading dose of 25 mg/kg on day 1, with subsequent IV doses of 12 mg/kg per day for the remainder of therapy. Azoles such as itraconazole and posaconazole are preferable to fluconazole for *Aspergillus* and zygomycetes. However, *Aspergillus* and zygomycetes are extremely rare in the NICU; therefore no studies have been done to recommend neonatal dosing guidelines.

Caspofungin, an echinocandin, has also been used in dosages of 25 mg/m² per day to treat invasive candidal disease in the newborn in several case reports. Caspofungin and other echinocandins such as micafungin (10 mg/kg per day) or anidulafungin (1.5 mg/kg per day) interrupt biosynthesis of β -(1,3)-D-glucan, an integral part of the fungal cell wall. However, identification of

infecting spp. has important implications for choice of therapy. Although amphotericin B formulations, the azoles, and the echinocandins are all appropriate for infections caused by *C. albicans*, non-*C. albicans* spp. such as *C. glabrata*, *C. guilliermondii*, and *C. krusei* may have decreased susceptibility to fluconazole and can be variably sensitive to the echinocandins (Odio et al., 2004; Sáez-Llorens et al., 2009; Hsieh et al., 2012). *C. lusitanae* is usually resistant to amphotericin B formulations.

Some experts recommend institution of empiric antifungal therapy in acutely thrombocytopenic neonates of less than 25 weeks' gestation, especially if there is a recent exposure to third-generation cephalosporins (Benjamin et al., 2003). Dosage adjustment for renal dysfunction is necessary only if serum creatinine increases significantly during therapy. Amphotericin B has poor cerebrospinal fluid penetration; in neonates with accompanying meningitis, fluconazole may also be added to amphotericin B. The use of 5-flucytosine in doses of approximately 25 mg/kg per dose (range 12.5–37.5 mg/kg) given orally every 6 hours in patients with normal renal function is no longer routinely recommended because of bone marrow suppression or hepatotoxicity when serum concentrations rise above 40 to 60 µg/mL.

With prompt removal of an offending CVC and no evidence of dissemination, the duration of therapy for catheter-associated candidemia is typically 10–14 days after the blood culture becomes negative (Donowitz and Hendley, 1995). Disseminated candidiasis, including *Candida* meningitis, requires at least three or more weeks of parenteral therapy; the course is typically completed when all foci have been eradicated. Most infectious disease experts will use fungicidal doses of parenteral amphotericin B or a liposomal preparation for the entire course.

Antifungal Prophylaxis

Five randomized controlled trials comparing IV fluconazole (3 mg/kg per day) with placebo or no treatment in VLBW or ELBW infants for 4 to 6 weeks (Kaufman et al., 2001; Kicklighter et al., 2001; Cabrera et al., 2002; Manzoni et al., 2007; Parikh et al., 2007) met criteria for analysis in Cochrane reviews (Clerihew et al., 2007). Kaufman et al. (2001) and Manzoni et al. (2007) reported significantly lower incidences of invasive fungal infection, while there was no difference in treated versus untreated infants in the studies of Kicklighter et al. (2001), Cabrera et al. (2002), and Parikh et al. (2007). The only study to evaluate neurologic outcomes found no difference in neurologic impairment at 16 months (Kaufman et al., 2001). Fluconazole prophylaxis did not affect a significant difference in the risk of death before discharge in any of the five studies or in a metaanalysis (Clerihew et al., 2007). No study documented clinically significant adverse effects of fluconazole or the emergence of fluconazole resistance.

One study from a single center compared nonrandomized fluconazole prophylaxis from 2002 to 2006 with an untreated, retrospective cohort from 2000 to 2001 and reported that invasive candidiasis decreased from 0.6% to 0.3%, although the proportion of invasive disease caused by non-*C. albicans* spp. increased from 26% to 41% after the introduction of fluconazole prophylaxis (Healy et al., 2008). Interestingly, fluconazole prophylaxis in this study was extended to several infants with birthweights greater than 1000 g, if risk factors (e.g., maternal human immunodeficiency virus infection, intestinal abnormalities) were present.

The finding that prophylactic fluconazole reduces the incidence of invasive fungal infection must be interpreted "with caution" (Clerihew et al., 2007; Clerihew et al., 2008) as:

1. The incidence of invasive fungal infection in the placebo groups in the Kaufman et al. (2001), Manzoni et al. (2007), and Parikh et al. (2007) studies was significantly higher (13%–16%) than in other large cohort studies of VLBW or ELBW infants in the United States (6%–7%) or the United Kingdom (1%–2%).
2. Fluconazole prophylaxis may have impaired the microbiologic isolation of some fungal spp. and led to underdiagnosis of infection in the treatment group.
3. Six years after the introduction of fluconazole prophylaxis, one study reported that non-*C. albicans* spp. with relatively reduced susceptibility to the azoles were the most common causes of invasive fungal infection (Parikh et al., 2007). This study did not detect a significant effect of fluconazole prophylaxis in reducing invasive candidal disease.

Current guidelines from the Infectious Diseases Society of America (Pappas et al., 2016) recommend IV or oral fluconazole, 3 to 6 mg/kg twice weekly for 6 weeks in neonates with birth weights less than 1000 g in nurseries with high rates (>10%) of invasive candidiasis. Oral nystatin, 100,000 units three times daily for 6 weeks, is an alternative in neonates less than 1500 g where issues with availability or resistance to fluconazole militate against its use.

Infections Ascribable to Other Fungi

Invasive Fungal Dermatitis

Invasive fungal dermatitis typically presents in the infant weighing less than 1000 g who displays macerated or bruised lesions that are contaminated with fungal spp.. In the initial report three of seven confirmed cases had *C. albicans*, *C. parapsilosis*, *C. tropicalis*, *Trichosporon beigelii*, *Curvularia*, or *Aspergillus niger* and *fumigatus* were cultured from the remainder (Rowen et al., 1995). Among cases considered "probable," seven of eight had *C. albicans*. Systemic complications, including fungemia, meningitis, or infection of the urinary tract, occurred in four of seven confirmed cases and seven of eight probable cases. More cases than controls had postnatal steroids and prolonged hyperglycemia. Disseminated infection occurred in 69%, all ascribable to *Candida* spp.

Diagnosis requires a skin biopsy demonstrating fungal invasion beyond the stratum corneum or a positive potassium hydroxide preparation of skin scrapings; growth of the identical organism from an otherwise sterile site (blood, cerebrospinal fluid, or urine obtained via suprapubic aspiration) is confirmatory. Treatment requires systemic doses of amphotericin B in the range of 0.7 to 1.0 mg/kg per day; in those infants who do not develop systemic infection, oral therapy with fluconazole or topical antifungal creams may suffice. Oral therapy is not advisable for pathogens like *Aspergillus*, and repeated skin biopsies may be necessary to define duration of therapy.

Line Infections Caused by Lipophilic Organisms

The spp. *M. furfur* and *M. pachydermatis* are lipophilic organisms commonly carried on the skin, even in patients without tinea versicolor (Marcon and Powel, 1992). Cutaneous colonization can infect hyperalimentation fluids or parenteral lipid formulations. Infants typically present with mild but nonspecific signs: respiratory decompensation, glucose intolerance, or thrombocytopenia (Dankner et al., 1987; Stuart and Lane, 1992). Diagnosis requires isolation of the organism from blood by growth on fungal medium overlaid with olive oil, since *Malassezia* spp. will not grow in the

absence of lipids (Marcon et al., 1986). Removal of the intravascular catheter usually suffices for therapy, although some experts recommend the addition of amphotericin B in doses of 0.5 mg/kg per day for 7 days.

Miscellaneous Fungal Infections

Aspergillus Species

Although rarely seen in neonates, systemic infection with *Aspergillus* suggests severe immunocompromise, such as in DiGeorge syndrome or myeloperoxidase deficiency (Chiang et al., 2000; Marcinkowski et al., 2000). Disseminated disease has occurred in premature newborns without additional immunologic abnormalities (Rowen et al., 1992). Diagnosis requires isolation of the fungus from a normally sterile tissue site or visualization by Gomori-methenamine silver stain on biopsy of infected tissue. Of note, a commercially available enzyme-linked immunosorbent assay for diagnosis of aspergillosis on serum specimens had an 83% rate of false positives in premature newborns (Siemann et al., 1998). Treatment requires systemic amphotericin B in doses of 1 mg/kg per day. Fungistatic therapies such as the triazoles are not recommended for aspergillosis.

Trichosporon beigelii

In a cluster of five neonatal cases of infection caused by *T. beigelii*, a yeast found ubiquitously in soil, no common source was identified (Fisher et al., 1993). Two of three premature neonates infected with this organism died. Resistance to achievable concentrations of amphotericin B complicates therapy.

Lung Development

ERIN PLOSA AND SUSAN H. GUTTENTAG

KEY POINTS

- Lung organogenesis is temporospatially organized into five stages, beginning at embryonic day 25 in humans.
- The mechanisms of lung organogenesis, including branching morphogenesis, stretch/mechanotransduction, alveolarization, microvascular maturation, and cellular differentiation, depend on transcriptional regulation of cell–cell and cell–extracellular matrix signaling networks.
- Alveolarization and lung growth are primarily postnatal processes that extend to early adulthood to establish a surface area that matches growing metabolic needs.
- A growing number of congenital lung malformations and acquired neonatal lung diseases can be traced to disruption of lung development.
- In addition to maturation of the surfactant system, development of lung host defense and environmental detoxification systems is critical for the transition from the fluid-filled fetal lungs to successful air breathing.

The primary function of the lung is to accomplish exchange of oxygen and carbon dioxide to accommodate the needs of aerobic cellular respiration. The oxygen consumption of the adult human ranges from 250 mL per minute at rest to 2630 mL per minute at peak exercise (Hansen et al., 1984). To accommodate these metabolic needs, a large surface area and a thin alveolocapillary membrane are required to enable efficient diffusion of oxygen, more so than carbon dioxide. Ultimately, the zone of gas exchange will attain a surface area of 50–100 m² and a volume of 2.5–3.0 L in the adult human. Therefore a primary goal of lung organogenesis is to expand the lung surface area to meet these needs. A second goal of lung organogenesis is to minimize the diffusion distance from the alveolus to the red blood cell, coordinating the development of an extensive capillary network with a thin, expansive alveolar epithelial surface. A third goal of lung development is production of a protective aqueous barrier overlying the delicate alveolar epithelium while mitigating the effects of the surface tension generated by this barrier, specifically alveolar collapse, through the production of a surface-active agent, or surfactant.

The trachea, airways, and alveoli are in constant contact with the external environment. Every inhalation brings large numbers

of microorganisms, and potentially toxic particles and gases, into direct contact with epithelial surfaces. Lung organogenesis must also incorporate mechanisms for clearance of microorganisms and allergens that may result in epithelial infection or injury. Similarly, the lung must defend against nonparticulate gases that are potentially harmful. Oxygen, so critical to cellular function, can be the source of harmful reactive oxygen species that require detoxification, as do inhaled pollutants. The appropriate development and maintenance of these lung functions are critical to the health and survival of newborns.

Key Events in Lung Development

Lung organogenesis begins early in human gestation (by day 25), and growth extends well into early adulthood (Kumar et al., 2005; Burri, 2006). Lung development is organized into stages (embryonic, pseudoglandular, canalicular, saccular, and alveolar), although the timing of these stages is somewhat imprecise, and considerable overlap may occur. Fig. 42.1 shows a time line of fetal and postnatal lung development in the mouse lung versus the human lung.

Development of Airways and Gas Exchange Surfaces

The initial phase of lung development, the *embryonic phase*, is marked by the formation of the lung bud and initial branching of presumptive airways. The lung bud is first recognizable as a laryngotracheal groove of the ventral foregut at 25 days of human gestation. Within a few days the groove closes such that the only remaining luminal attachment to the foregut is in the region of the developing hypopharynx and larynx. The lung bud, consisting of epithelium and surrounding mesenchyme, then begins the first of a series of dichotomous divisions that give rise to the conducting airways and five primordial lung lobes (two on the left and three on the right). Tracheoesophageal fistulae, tracheal atresia, and tracheal stenosis result from errors in separation of the laryngotracheal groove, whereas failure of partitioning of the lung bud can result in pulmonary agenesis, most typically of the right lung (Jacobs et al., 2012). Branching continues into the *pseudoglandular stage* of lung development. By 7 weeks of human gestation, the trachea, segmental bronchi, and subsegmental bronchi are evident. By the end of 16 weeks, all bronchial divisions are completed. It is important to remember that although the conducting airways

• **Fig. 42.1** Comparison of Lung Development Events in Mice and Humans. Lung endoderm specification begins at embryonic day 9 in the mouse, and the development stages in the mouse are depicted associated with key transcription factors. Comparisons are provided with the timing of equivalent events in human lung development, beginning at day 25 of gestation in the human. Ca, Caudal; Ce, cephalic; D, dorsal; L, left; R, right; V, ventral. (Modified from Herriges M, Morrisey EE. Lung development: orchestrating the generation and regeneration of a complex organ. *Development*. 2014;141:502–513.)

will certainly enlarge as the fetus and newborn grow (airway diameter and length increase twofold to threefold between birth and adulthood), large airway branching ceases after 16 weeks of human gestation.

Closure of the pleuroperitoneal folds is a critical event of the pseudoglandular phase, reaching completion by 7 weeks and resulting in separation of the thoracic cavity from the peritoneal cavity. Failure of pleuroperitoneal closure results in a diaphragmatic defect and continuity between these cavities, resulting in herniation of abdominal contents into the thorax when the midgut returns to the peritoneal cavity from the umbilical cord at 10 weeks of human gestation. The resulting congenital diaphragmatic hernia leads to pulmonary hypoplasia of the lung ipsilateral to the diaphragmatic defect as bowel and solid viscera migrate into the thorax. Pulmonary hypoplasia may also extend to the contralateral lung as the mediastinum shifts because of accumulating abdominal viscera in the thorax.

The *canalicular phase* is marked by completion of the conducting airways through the level of the terminal bronchioles and the development of the rudimentary gas exchange units that are no longer invested with cartilaginous support. The acinus is the gas exchange unit of the lung and encompasses a respiratory bronchiole and all of its associated alveolar ducts and alveoli. A terminal bronchiole with all its associated acinar structures constitutes a lobule. Branching of these distal air spaces continues on a more limited basis during the canalicular phase, finally achieving a total of 23 airway subdivisions.

Evolution of the relationships between the air spaces, capillaries, and mesenchyme takes on more significance during the *saccular phase* of lung development (24–38 weeks of human gestation), enabling an alveolocapillary membrane sufficient to participate in

gas exchange ($0.6\ \mu\text{m}$) by approximately 24 weeks of human gestation. Beyond this point the efficiency of gas exchange is determined by the available surface area. Lengthening and widening of the terminal sacs expand the gas-exchange surface area. Each saccule consists of smooth-walled air spaces with thickened interstitial spaces containing a double capillary network. These will give rise to two or three alveolar ducts, further expanding the available surface area. Expansion of these rudimentary gas exchange units continues well into the third trimester of human gestation. Thus the human lung is not fully mature structurally, even at term delivery.

Postnatal lung development can be subdivided into additional stages (Burri, 2006). True alveoli become evident as early as 36 weeks of gestation in the human fetus, initiating the *alveolar phase* of lung development. The development of primary alveoli is followed by a further expansion of the gas-exchange surface area through the formation of septae, or secondary crests (described further later). Postnatal alveolarization extends from term through 1–2 years of age. An initial phase of “*bulk alveolarization*” occurs within the first 6 months postnatally, with a more modest addition of secondary alveoli through the remainder of this period. The alveoli of the infant lung are different from adult alveoli. These immature secondary alveoli contain a double capillary bed, whereas adult alveoli are invested by a single capillary bed. *Microvascular maturation*, the next phase of postnatal lung development, occurs between the first few postnatal months of life through 3 years of age (discussed later).

There is considerable controversy regarding when the lung ceases to add alveoli. Estimates have ranged from as early as 2 years to as late as 20 years of age in humans (Narayanan et al., 2012). This is further complicated by the observation that alveolar expansion

can occur in response to pneumonectomy in adult animals (Hsia et al., 1994) and humans (Butler et al., 2012). The acquisition of alveoli after the maturation of the microvasculature has been termed *late alveolarization*. This activity has been most often demonstrated in subpleural regions of the lung and likely invokes mechanisms similar to secondary crest formation.

The addition of alveoli is not the only means for expanding the surface area of the lung. While alveolarization wanes over the first 3 years of life in the human, *growth of the lung* continues to expand the gas-exchange surface area. Between 2 years of age and adulthood, lung tissue expands with lung volume proportionately to the increase in body weight of the child. Hyperpolarized helium-3 diffusion magnetic resonance imaging, a noninvasive means of assessing alveolar volume, has been used in children as young as 4 years to demonstrate increasing lung volume during childhood and adolescence (Altes et al., 2006). The observed increase in the apparent diffusion coefficient suggests that expanding lung volume is due to not only increasing numbers of alveoli but also increasing size of alveoli. Thus owing to the combined processes of prenatal lung development, postnatal lung development, and lung growth, there is tremendous potential for expansion of the gas-exchange surface area that is developmentally programmed into the fetal lung to account for the growing needs of the infant, child, and adult for aerobic cellular respiration. The extent to which these developmental mechanisms can be harnessed after premature birth, with or without superimposed lung injury, is a topic of active investigation that relies on extrapolation of experimental data from mice.

Composition of Airways and Alveoli

As branching morphogenesis proceeds, the epithelium lining the successive generations of airways and alveoli gives rise to specialized cells that participate in gas exchange, surfactant production, mucociliary clearance, detoxification, and host defense. Differentiation proceeds in a centrifugal fashion from proximal air spaces to distal air spaces, lagging behind branching. Temporal as well as contextual signals foster the regionalization of epithelial cell types.

Proximal Airways

The airway epithelium is tall and columnar, decreasing to a more cuboidal appearance more distally (Jeffery, 1998). The endodermal epithelial lining cells of the trachea and bronchi partition into four cell types: undifferentiated columnar, ciliated, secretory/goblet, and basal cells. Ciliated cells critical to the process of mucus clearance are first apparent between 11 and 16 weeks of human gestation and become less prevalent in more distal airways. Three types of secretory cells—those with largely mucous granules, those with serous granules, and some with both types of granules—can be seen as early as 13 weeks of human gestation. The number of mucin-producing goblet cells in airways peaks at midgestation in the fetus and declines in the third trimester relative to adulthood. Finally, immature basal cells expressing epidermal keratin have been noted as early as 12 weeks of human gestation. Basal cells play a critical role in regenerating injured large airway epithelium.

Cartilaginous support of the tracheobronchial tree begins and also proceeds in a centrifugal fashion beginning in the primitive trachea at 4 weeks, reaching the main bronchi by 10 weeks, and proceeding to the most distal terminal bronchioles by approximately 25 weeks of human gestation. Cartilaginous investment of airways is complete by the second month postnatally. Submucosal glands found in the interstitium between the cartilaginous tissue and

surface epithelium play a major role in airway host defense. Submucosal gland development can be characterized by five stages: epithelial budding and invasion of the lamina propria, development of a lumen, initiation of tube branching, and repetitive dichotomous branching. The airways of infants and children contain relatively more submucous glands than those of adults. The glands are lined by mucous cells proximally and serous cells more distally, the latter constituting 60% of the total epithelial cell content of the glands. Serous cells secrete water, electrolytes, and proteins with antimicrobial, antiinflammatory, and antioxidant properties, while the mucous cells produce primarily mucins. In addition to this host defense role, submucosal glands also contain a population of basal cells that respond to injury of the airway by replenishing the airway epithelium.

Muscular investment of the airways begins as early as 6–8 weeks of gestation as smooth muscle cells are identifiable around the trachea and large airways. Fetal airway smooth muscle is innervated and able to contract during the first trimester. It contracts in response to methacholine challenge, and this is reversible with β -adrenergic agonists. Muscularization increases throughout fetal life and childhood such that there is an increased amount of smooth muscle relative to airway size when compared with adult airways. Moreover, the rapid increase in the amount of bronchial smooth muscle immediately after birth occurs regardless of the timing of delivery, term or preterm.

An additional airway cell deserves mention because of its association with a wide variety of pediatric diseases. Pulmonary neuroendocrine cells (PNECs) are found throughout the airways, often in innervated clusters known as *pulmonary neuroepithelial bodies* (NEBs) located at branch points in the bronchial tree (Gu et al., 2014; Cutz, 2015). Although they arise from foregut endoderm, the cell of origin is distinct from other epithelial components of the lung. PNECs have large numbers of dense core vesicles containing neuropeptides, including serotonin and calcitonin gene-related peptide/bombesin, and regulate bronchial tone by releasing their contents in response to stretch- and hypoxia-mediated stimuli. Recent evidence suggests that PNECs also function as airway sensors that trigger immune responses (Branchfield et al., 2016). Pathologic conditions associated with PNEC/NEB hyperplasia include bronchopulmonary dysplasia (BPD), disorders of respiratory control (congenital central hypoventilation syndrome and sudden infant death syndrome), cystic fibrosis, chronic obstructive pulmonary disease, congenital diaphragmatic hernia, and pulmonary hypertension. Neuroendocrine hyperplasia of infancy is a rare form of interstitial lung disease of infancy associated with expansion of the number of PNECs and NEBs. Although the associations are strong, it remains unclear whether PNECs/NEBs play a primary role in these diseases or a responsive secondary role.

Distal Airways

The bronchiolar epithelium differs from the more proximal airway epithelium. In addition to being more cuboidal in appearance, the epithelium contains progressively fewer ciliated cells and goblet cells, which are ultimately absent from the terminal bronchioles. Instead, the nonciliated, secretory club cell is found in increasing numbers and density down the conducting airways, such that the club cell is the most abundant cell of the terminal bronchiole (Jeffery, 1998). Club cells are first evident by 16–17 weeks of human gestation, initially exhibiting large glycogen stores that are replaced by secretory granules. Between 23 and 34 weeks of gestation there is a dramatic increase in club cell numbers in distal bronchioles.

Club cells are critical to the host defense and detoxification functions of the lung. This specialized cell produces the highest levels of cytochrome P450 and flavin monooxygenases in the lung. While critically important in detoxification, these enzymes also participate in the bioactivation of procarcinogens, placing the club cell in a precarious position as a primary target of toxic metabolites. The club cell also plays an important role in immunoregulation in the distal airways. Important host defense products of the club cell include club cell secretory protein, surfactant protein A (SP-A), surfactant protein D (SP-D), leukocyte protease inhibitor, and a trypsin-like protease. Club cells produce a precursor form of surfactant protein B (SP-B) that may contribute to host defense. The secretion of antiproteases from club cells suggests that they modulate the protease–antiprotease balance in the distal part of the lung.

Alveolar Epithelium

During the fourth through sixth month of human gestation the epithelial cells lining the acini begin to differentiate further (Khoor et al., 1994). The cuboidal epithelial cells accumulate large glycogen stores and develop small vesicles containing loose lamellae. The large glycogen pools provide a ready source of substrate required for the production of increasing amounts of surfactant phospholipids, and they decrease in size as surfactant production advances in the fetal lung. In cells destined to become type 2 cells, lamellar bodies become larger, more numerous, and more densely packed with surfactant phospholipids and proteins, whereas those cells destined to become type 1 cells, on losing their prelamellar vesicles and becoming progressively thinner, adopt a phenotype more suitable for gas exchange. Alveolar type 1 and type 2 cells are readily identified early in the sacular stage of fetal lung development. There remains considerable controversy regarding the origin of type 1 epithelial cells. These cells in culture demonstrate very slow turnover, with a doubling time estimated to be between 40 and 120 days, suggesting that functionally they are terminally differentiated *in vivo*. Furthermore, in response to epithelial denudation occurring with lung injury, type 2 cells rapidly proliferate to reestablish epithelial continuity and then lose phenotypic features such as lamellar bodies and acquire markers of type 1 cells, suggesting that rapid repopulation of type 1 cells requires a type 2 cell intermediary. More recent studies in animals have suggested that alveolar type 1 cells can be induced to exit their terminally differentiated state and proliferate (Yang et al., 2016).

There is increasing appreciation for the alveolar type 1 cell as more than just a passive membrane for gas exchange (Williams, 2003). While a large surface area and small cytoplasm-to-nucleus ratio provides a thin alveolocapillary membrane to facilitate gas exchange, it also provides a large absorptive surface in the lung. The presence of water and ion channels, some distinct from those in type 2 cells, facilitates the maintenance of a relatively dry alveolus. Type 1 cells may also regulate cell proliferation locally, signal macrophage accumulation, and modulate the functions of local peptides, proteases, and growth factors.

While most notable for its role in surfactant production (discussed later), the alveolar type 2 cell provides other important functions in the alveolus (Fehrenbach, 2001). Alveolar type 2 cells are local progenitor cells and, like type 1 cells, contain ion and water channels as well as ion pumps that contribute to the movement of water and ions across the epithelium. Type 2 cells also contain and secrete important antioxidants (superoxide dismutases 1, 2, 3 and glutathione) and molecules of innate host defense (SP-A,

SP-D, and lysozyme) to participate in detoxification and sterilization of the alveolar microenvironment.

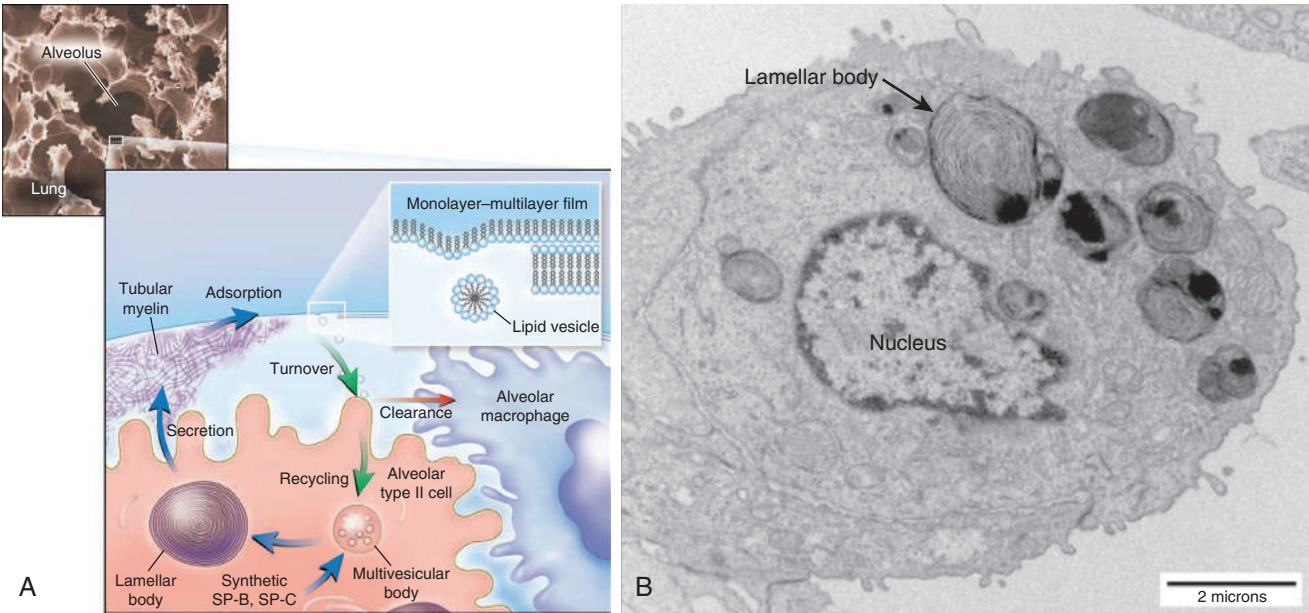

More recently, it is becoming clear that alveolar type 2 cells may play a part in exacerbating alveolar disease. The type 2 cell participates in the coagulation–fibrinolysis cascade through the production of fibrinogen, urokinase-type plasminogen activator, and tissue factor, especially under pathologic circumstances. Type 2 cells are increasingly recognized as a source of cytokine and chemokine production in the lung, as well as growth factors that can promote fibrosis. Finally, cross talk between epithelial cells, cell matrix, interstitial cells, and local inflammatory cells can foster the resolution of injury and inflammation or prolong lung remodeling after injury, with detrimental effects such as lung destruction and fibrosis. Therefore while previously heralded as the defender of the alveolus, the alveolar type 2 cell plays a much more complex role in alveolar health and disease.

Surfactant

Pulmonary surfactant is essential to alveolar health. The alveolar epithelial cells secrete a thin layer of liquid to protect the gas-exchange surface. The surface tension generated by this aqueous layer opposes alveolar inflation and promotes alveolar collapse at the end of expiration owing to the law of Laplace, whereby the collapsing pressure on the alveolus is directly proportional to the surface tension and inversely proportional to the radius of the alveolus. The film of pulmonary surfactant at the air–liquid interface lowers surface tension as the alveolar surface area decreases with exhalation, thereby preventing end-expiratory atelectasis, maintaining functional residual capacity, and lowering the force required for subsequent alveolar inflations.

Pulmonary surfactant is a complex mixture of phospholipids, neutral lipids, and proteins that is synthesized, packaged, and secreted by alveolar type 2 cells (Whitsett et al., 2015). The life cycle of surfactant is depicted in Fig. 42.2. Storage of surfactant occurs in the lamellar body, a lysosome-derived membrane-bound organelle that undergoes regulated secretion in response to a variety of stimuli, including stretch. In the alveolus, surfactant phospholipids transition through an extracellular storage form, tubular myelin. Phospholipid and protein components are recycled out of the surfactant monolayer at the air–liquid interface and taken back into the alveolar type 2 cell, where they can be repackaged into lamellar bodies. Alternatively, alveolar macrophages are able to engulf and degrade surfactant components.

The predominant surfactant phospholipid is saturated dipalmitoyl phosphatidylcholine (DPPC), with the remaining phospholipids consisting of monounsaturated phosphatidylcholine, phosphatidylglycerol, and other phospholipids (Table 42.1; Parra and Perez-Gil, 2015). DPPC is the only surface-active component of lung surfactant capable of lowering surface pressure to nearly zero. The presence of unsaturated phospholipids and other lipid components such as cholesterol enables the monolayer to remain fluid at body temperature during the respiratory cycle. Phospholipid content in the fetal lung increases with advancing gestation because of increased activity of enzymes responsible for phospholipid synthesis within alveolar type 2 cells. The expression and activity of enzymes of the choline incorporation pathway, the predominant pathway for surfactant phospholipid synthesis, are not only developmentally regulated but are also induced by hormones. The inductive hormones that have direct clinical relevance are glucocorticoids and agents that increase intracellular cyclic AMP

TABLE 42.1 Composition of Pulmonary Surfactant

| Component | Percentage (by Weight) |
|---------------------------------|------------------------|
| Lipid | 92 |
| Saturated phosphatidylcholine | 41 |
| Unsaturated phosphatidylcholine | 25 |
| Phosphatidylglycerol | 9 |
| Other phospholipids | 4 |
| Cholesterol | 8 |
| Neutral lipids | 5 |
| Protein | 10 |
| Surfactant proteins | 8 |

(cAMP) levels such as the β -adrenergic agonist (and tocolytic) terbutaline.

Surfactant contains a group of specific proteins with importance for surfactant function and host defense. The four surfactant proteins, SP-A, SP-B, surfactant protein C (SP-C), and SP-D, are subdivided on the basis of their physical characteristics into either hydrophobic (SP-B and SP-C) or hydrophilic (SP-A and SP-D) proteins. The hydrophobic surfactant proteins play a major role in the surface-active properties of surfactant, whereas the primary roles of the hydrophilic surfactant proteins are in host defense, immunomodulation, and surfactant clearance and metabolism.

Together the hydrophobic proteins, SP-B and SP-C, facilitate the mobilization of surfactant phospholipid from tubular myelin to the surface monolayer, promote spreading of phospholipids in the surfactant film, and assist in film stability at the end of expiration. SP-B plays a central role in alveolar health because of its critical function in surfactant homeostasis. SP-B is a secretory protein that exhibits strong association with membranes, unlike

SP-C, which contains a membrane-spanning domain and covalently attached fatty acids (palmitate) that render it integral to phospholipid membranes (Conkright et al., 2001). Both SP-B and SP-C are synthesized as large precursor proproteins that undergo extensive posttranslational processing as they pass through the secretory pathway, ultimately reaching the lamellar body. SP-B is essential for the process of lamellar body formation, and the alveolar type 2 cells of infants with an inherited deficiency of SP-B are devoid of lamellar bodies. Because the lamellar body is where SP-C proteolytic processing is completed, infants with inherited deficiency of SP-B are also deficient in mature SP-C, instead accumulating a larger, nonfunctional precursor of SP-C. Thus patients with inherited deficiency of SP-B, despite having relatively normal surfactant phospholipid profiles, make a pulmonary surfactant with very poor surface tension properties because of the combined defects in SP-B and SP-C. Conversely, because SP-C does not play either a direct or an indirect role in SP-B processing, animals with SP-C deficiency have normal SP-B, have normal lamellar bodies, and exhibit no perinatal lethality due to surfactant dysfunction.

Like the enzymes of surfactant phospholipid production, SP-B and SP-C exhibit developmental and hormonal regulation of expression (Mendelson, 2000). In human fetuses, SP-C messenger ribonucleic acid (mRNA) is detected as early as 12 weeks of gestation and SP-B mRNA by 14 weeks, yet the mature proteins are not detectable in fetal lung tissue until after 24 weeks. SP-B protein is not detectable in amniotic fluid until after 30 weeks of gestation, the amount increasing toward term (Pryhuber et al., 1991). This is due to developmental regulation of posttranslational events in the proteolytic processing of proSP-B and proSP-C (Guttenag, 2008). Consequently, infants delivered prematurely have reduced levels of both surface-active components of surfactant—phospholipid and hydrophobic surfactant proteins. The rate of type 2 cell differentiation, and secondarily surfactant production, is modulated

by the levels of endogenous corticosteroids and is accelerated by prenatal administration of glucocorticoid to women in preterm labor. The response of the surfactant system to prenatally administered glucocorticoids involves all key lipid and protein components, and occurs primarily through increased gene expression, thus representing precocious maturation mimicking the normal developmental pattern. Endogenous thyroid hormones, prostaglandins, and catecholamines also have stimulatory effects on type 2 cell maturation as well as on clearance of lung fluid at birth. Certain proinflammatory cytokines (e.g., tumor necrosis factor (TNF)- α and transforming growth factor (TGF)- β) inhibit surfactant production in experimental systems and may downregulate surfactant in conditions such as sepsis and inflammation.

Development of the Pulmonary Vasculature

The primary role of the pulmonary vasculature is to supply blood flow to the acini for gas exchange (Peng and Morrissey, 2013). During early fetal life the airways act as a template for pulmonary blood vessel development. The earliest pulmonary vessels form *de novo* in the tissue surrounding the lung bud in a process known as *vasculogenesis*. Mesodermal cells within the mesenchyme investing the developing lung tube differentiate into endothelial cells, proliferate, organize into chords, and develop a central lumen. As each new airway buds into the mesenchyme, a new plexus forms that adds to the pulmonary circulation, thereby extending the network of arteries and veins. By the fifth week of human gestation, a capillary network surrounds each bronchus, and circulation of blood between the right ventricle and the left atrium via this network is evident.

During the canalicular stage of lung development, new blood vessels form from preexisting vessels, a process known as *angiogenesis*. In contrast to *vasculogenesis*, *angiogenesis* is initiated by endothelial cell proliferation and sprouting from established vessels, resulting in extension of a vascular network into undervascularized regions. *Vasculogenesis* is the primary mode of pulmonary vascular development until the 17th week of gestation, when all preacinar airways and their accompanying vessels are present, whereas *angiogenesis* becomes the predominant mode of vascular development in the later stages of lung development. Although originally thought to be sequential processes, it is generally accepted that both occur concurrently during lung development, with *angiogenesis* dominating in the central part of the lung and *vasculogenesis* dominating in the periphery (deMello et al., 1997). Interconnections between vascular networks arising from both *angiogenesis* and *vasculogenesis* increase in the saccular phase of lung development.

In the human lung a second circulatory system, the bronchial circulation, arises from the dorsal aorta and nourishes the cellular constituents of the lung itself. The bronchial vasculature develops after the pulmonary circulation, with bronchial vessels first apparent by 8 weeks of gestation. The network of bronchial vessels is extensive, with bronchial arteries demonstrated as distal as the alveolar ducts in the adult respiratory tree. Inappropriate branching of bronchial vessels from the dorsal aorta is implicated in the formation of bronchopulmonary sequestration, a space-occupying lung malformation that can result in hypoplasia of the ipsilateral lung.

Vasculogenesis and *angiogenesis* are the primary mechanisms of vascular development throughout intrauterine life. The human lung at term contains only a small portion of the adult number of alveoli, and the air space walls are represented by a thick "primary septum" consisting of a central layer of connective tissue surrounded by two capillary beds, each of them facing one alveolar surface

(Burri, 2006). As alveolar architecture changes with the appearance of secondary septa, or secondary crests, folding of one of the two capillary layers occurs within the secondary septa. Microvascular maturation involves fusion of the juvenile double capillary network into a single capillary system present in the adult lung. Fusion is facilitated by the expansion of alveolar surface area and luminal volume, which compresses the interstitium, bringing the capillary networks in close proximity. This process is evident in the third postnatal week, during which lung volume increases by 25%, with a concomitant 27% decrease of the interstitial tissue volume. Subsequently, preferential growth of areas with a mature, fused capillary system continues.

Lastly, it is well known that lung volume increases about 23-fold between birth and young adulthood, while capillary volume expands 35-fold. It has been shown recently that this increase in capillary volume occurs by a third mechanism of vascular development: intussusceptive microvascular growth. This new concept in capillary network growth involves the formation of transluminal tissue pillars within capillaries that then expand, resulting in a net increase in capillary surface area (Burri, 2006).

Muscularization of the pulmonary arteries begins early in development (Hislop, 2005). Initially the muscular investment of the vasculature is derived from the migration of bronchial smooth muscle cells from adjacent airways. Muscularization of preacinar and resistance arteries of the pulmonary vasculature begins in the canalicular stage and continues through the remainder of gestation. This second phase of smooth muscle cells investing pulmonary vessels develops from the surrounding mesenchyme. Fibroblasts in close proximity to developing arteries alter their cellular shape and begin to express α -smooth muscle actin, a marker of their transformation into smooth muscle cells. A third phase of vascular muscularization, largely restricted to the distal part of the lung, involves the process of endothelial-mesenchymal transition, marked by endothelial cell division, separation and migration away from the endothelial layer, and expression of smooth muscle cell markers.

Muscularization of pulmonary arteries normally extends to the level of the terminal bronchiole and is minimal to absent in blood vessels surrounding respiratory bronchioles. Abnormal extension of smooth muscle along arterioles supplying acinar structures occurs in infants dying of persistent pulmonary hypertension of the newborn, as well as in infants with congenital diaphragmatic hernia and severe BPD.

Development of Pulmonary Host Defense

Every minute, the adult human lung takes in approximately 7 L of air contaminated with a variety of potential pathogens that can cause lung injury. The continuous exposure of the epithelial surface of the conducting airway to inhaled pathogens requires the presence of an efficient innate immune response system as a first-line defense against infection. The proximal and distal airway epithelia play a major role in clearing pathogens by secreting antimicrobial as well as antiinflammatory molecules into the airways and alveoli. In the proximal airways, components of mucociliary clearance appear as early as 11 weeks of human gestation, including ciliated epithelial cells, goblet cells expressing mucins, and submucosal glands described previously. The relative increase in the number of airway goblet cells over ciliated cells in prematurely born infants compared with term infants renders premature infants more prone to enhanced mucus production and obstruction caused by poor mucociliary clearance.

A number of microbial defense molecules are produced and secreted by epithelial cells into the airways (Bartlett et al., 2008). They include lysozyme, C-reactive protein, lactoferrin, collectins, β -defensins, and the cathelicidin CAP-18/LL-37 (Hiemstra, 2007). Two lung collectins originally identified as surfactant-related proteins, SP-A and SP-D, play a larger role in lung host defense than in surfactant biophysics. Although originally identified as products elaborated by epithelial cells lining airways (club cells) and alveoli (type 2 cells), they are secreted at other epithelial surfaces exposed to the external environment (Haagsman and Diemel, 2001; Kim et al., 2007; Bräuer et al., 2012; Madhukaran et al., 2015). These collectins interact with microorganisms and inflammatory cells to facilitate microorganism clearance and modulate inflammatory and apoptotic responses (Goto et al., 2014).

The basis for the interactions of the lung collectins with microbes and antigens centers on the binding of sugars by the carbohydrate recognition domains of these proteins (Wright, 2005). Interactions between collectins and gram-negative bacteria depend on the ability of SP-A and SP-D to bind lipopolysaccharide, whereas interactions with gram-positive bacteria, including group B β -hemolytic streptococcus, depend on recognition of the gram-positive outer membrane component lipoteichoic acid (Liu et al., 2012). The collectins bind a variety of fungi as well as *Pneumocystis carinii* and play an important role in inhibiting a variety of respiratory viruses, including influenza A virus and respiratory syncytial virus. Differences in the structure of the carbohydrate recognition domain provide SP-A and SP-D with altered affinities for different sugar molecules, allowing complementary functions and improving the diversity of microbial interactions.

The lung collectins also modulate the functions of a variety of immune cells, including macrophages, neutrophils, eosinophils, and lymphocytes (Atochina et al., 2004; Douda et al., 2011; Ariki et al., 2012). The collectins enhance the local production of chemotactic factors to attract macrophages and neutrophils and cytokines that activate macrophages and eosinophils, as well as attenuate lymphocyte responses by inhibiting T-cell proliferation. Other direct effects on inflammatory cells include modulating the production of reactive oxygen and nitrogen species used in killing microorganisms.

Like the hydrophobic surfactant proteins, SP-A and SP-D exhibit both developmental and hormonal regulation of expression (Mendelson, 2000). In human fetuses, SP-A mRNA is undetectable before 20 weeks of gestation, and SP-A is first detectable in amniotic fluid by 30 weeks of gestation, with the amount increasing toward term (Pryhuber et al., 1991). The SP-A gene promoter is induced by cAMP and glucocorticoids, although the response to glucocorticoids is biphasic, showing attenuation of SP-A expression at higher doses. Retinoids, insulin, and growth factors, including TGF- β and TNF- α , inhibit SP-A gene expression. Like SP-A, SP-D expression in the developing lung is quite low during the second trimester (Dulkerian et al., 1996) but is detectable in amniotic fluid in the third trimester, increasing toward term. The levels of both SP-A and SP-D increase markedly in the first few days after preterm birth and can be modulated by the local microenvironment of pathogens, toxins, and reactive oxygen species (Park et al., 2012; Zou et al., 2016).

Development of Detoxification Systems

Although oxygen is an essential component of cellular processes, concentrations beyond the physiologic limits may be hazardous to cells. The lung is particularly susceptible to reactive forms of

oxygen and free radicals since it is the organ with the highest exposure to atmospheric oxygen. The fetal lung is exposed to oxygen tensions of 20–25 mmHg in utero, and the transition to air breathing is associated with a fourfold to sevenfold increase in oxygen tension, presenting a significant oxidant stress. Oxygen free radicals arise from endogenous production through metabolic reactions or by exogenous exposure, such as air pollutants and cigarette smoke. Free radicals injure the lung through oxidation of proteins, DNA, and lipids. Therefore an antioxidant detoxification system is especially critical during the transition of the fetal lung to air breathing.

Oxygen free radicals are highly toxic substances. Superoxide is produced by the reduction of molecular oxygen through the addition of an electron, hydrogen peroxide is produced from the transfer of a single electron to superoxide, and hydroxyl radicals are produced through the interaction of hydrogen peroxide with superoxide. The free electrons of free radicals promote peroxidation of membrane lipids, alter sulfhydryl and other groups on exposed amino acids in proteins, and cause direct damage to DNA. All of these changes have been described in the lungs of animals and humans exposed to high levels of oxygen, although the dose response differs by species and with age, leading to altered epithelial integrity, interstitial and air space edema, and infiltration of inflammatory cells. Reactive oxygen species have also been implicated in enhancing production of proinflammatory mediators by lung epithelial and resident inflammatory cells, through chromatin remodeling, triggering signal transduction pathways, and activating transcription factors (Iliodromiti et al., 2013; Porzionato et al., 2015).

Antioxidants, both nonenzymatic and enzymatic, attenuate the effects of oxygen free radicals in the lungs. The major nonenzymatic antioxidants are glutathione, vitamin C (ascorbate), vitamin E (primarily α -tocopherol), β -carotene, and uric acid. Enzymatic antioxidants include superoxide dismutases (1, 2, and 3), catalase, thioredoxins, and a variety of peroxidases. Animal studies indicate that many of the antioxidant enzymes are induced before term delivery, and limited data suggest that the same is true for human fetuses (Weinberger et al., 2002). However, premature animals fail to induce antioxidant enzymes in response to oxidative lung injury (Berkelhamer and Farrow, 2014). Thus preterm infants are at significantly higher risk of oxidant lung injury owing to both increased need for oxygen in the treatment of respiratory distress syndrome and underdeveloped antioxidant defenses.

Mechanisms of Lung Development

Fetal and postnatal lung development depend on several key developmental processes: branching morphogenesis to promote branching of the lung bud into the surrounding mesenchyme, static and cyclic stretching of the lung that assist in promoting sacculization, alveolarization to enhance the expansion of the gas-exchange surface area, and vasculogenesis and angiogenesis to ensure that the developing epithelial surface area is invested with both a gas-exchange and a nourishing vascular supply.

Branching Morphogenesis

Branching morphogenesis is a fundamental mechanism of lung development. Branching is mediated by the accelerated growth of epithelial cells along the stalk of a branching airway with concomitant growth arrest at the branch tip (Affolter et al., 2009). This process requires extensive communication between epithelial cells and with the adjacent mesenchyme, as well as integration of

microenvironmental cues from the extracellular matrix (McCulley et al., 2015). Classic tissue recombination experiments in which mesenchyme from proximal airways was transplanted to distal airways (and vice versa) indicate that the mesenchyme has an important inductive role in dictating the branching pattern and cell fate of the expanding epithelium (Alescio and Dani, 1971). More recently, elegant studies using genetic mouse models indicate that three modes of branching—domain branching, planar bifurcation, and orthogonal bifurcation—are the basic mechanisms that characterize development of the complex three-dimensional respiratory tree through the pseudoglandular phase (Metzger and Krasnow, 1999; Metzger et al., 2008). These branching patterns are used repetitively during lung development and appear to be governed by a genetic clock orchestrating side branch formation, then planar bifurcation of a side branch, and planar rotation dictating the orientation of the bifurcation, thereby establishing a complex, three-dimensional structure.

Stretch and Mechanotransduction

The role of physical factors in modulating lung size is well established: normal lung growth requires adequate space in the chest cavity and appropriate tonic and cyclic distending forces. Genetic defects that compromise the thoracic skeleton and space-occupying lung masses such as congenital cystic adenomatoid malformations are associated with pulmonary hypoplasia due to the restriction of intrathoracic space. Denervation of the diaphragm to eliminate fetal breathing movements is associated with pulmonary hypoplasia, as is oligohydramnios.

Static Stretch: Fetal Lung Fluid Production

Fetal lung fluid is a product of the epithelial lining of the developing lung (Wilson et al., 2007; Helve et al., 2009), averaging 4–6 mL/kg per hour. The resistance imparted by laryngeal abduction results in fluid accumulation to a total volume of 20–30 mL/kg during gestation, which generates an end-expiratory pressure of approximately 2–4 cmH₂O. The composition of fetal lung fluid is distinct from that of both amniotic fluid and plasma, as illustrated in Table 42.2. The increased chloride content of fetal lung fluid as compared with serum is the result of active chloride secretion by the tracheal and distal pulmonary epithelium, largely because of the chloride channel CLC-2/CLCN2. A variety of growth factors, hormones, and lipid mediators influence the production of fetal lung fluid during gestation, including enhancers (prolactin, keratinocyte

growth factor, prostaglandin E₂, and prostaglandin F₂) and inhibitors (β-adrenergic agonists, vasopressin, serotonin, and glucagon).

While fetal lung fluid is an essential component of lung development, it presents a significant obstacle to the transition to air breathing on delivery. Three important events must occur to minimize the amount of fetal lung fluid and its potential impact on alveolar surface tension before the transition to air breathing: absorption, bulk removal, and maturation of pulmonary surfactant. Conversion of the pulmonary epithelium from a secretory to an absorptive surface is a critical event during the third trimester. Enhanced sodium transport across the alveolar epithelium is in part responsible for this change. Much evidence suggests that increasing expression of components of the epithelial sodium channel (ENaC) in the third trimester is a major factor in promoting sodium reabsorption from alveoli, with water passively following the movement of sodium (Helve et al., 2009; Hummler and Planès, 2010). Transgenic mouse pups that do not express the α subunit of ENaC die quickly after birth because of failure of fetal lung fluid clearance. Induction of ENaC subunits occurs at a transcriptional level in response to changes in extracellular matrix components, glucocorticoids, aldosterone, and oxygen. Drugs that increase intracellular cAMP levels (i.e., β-adrenergic agonists, phosphodiesterase inhibitors, and cAMP analogues), while not increasing the number of ENaC channels, increase the probability of a channel being open to sodium transport. In addition, glucocorticoid and thyroid hormones play an important role in priming the lung epithelium to be responsive to the actions of β-adrenergic agonists on sodium transport across lung epithelia near term. Thus the prenatal use of glucocorticoids and tocolytics may improve lung function in prematurely born infants through enhanced lung fluid reabsorption as well as by increasing surfactant production. Epithelial water channels, consisting of aquaporin proteins, are also induced during the late fetal period (Liu and Wintour, 2005). While water channels are clearly essential for fluid movement across epithelial cell membranes, their importance for fetal lung fluid clearance is less certain in the face of perinatal survival of transgenic mouse pups that do not express aquaporin 5 and/or aquaporin 1.

Conversion to an absorptive surface is not enough to minimize the amount of fetal lung fluid at the time of term delivery. The absence of uterine contractions is associated with an increased incidence of retained fetal lung fluid in infants born by cesarean delivery without the benefit of labor. On delivery of the head and neck, continued uterine contractions on the fetal thorax promote expulsion of bulk fluid from the fetal lung. However, animal studies suggest that the magnitude of the benefit of thoracic compression during labor is modest (Bland, 2001). Instead, the primary mechanism by which labor facilitates clearance of lung fluid is through hormonal effects on fluid clearance, especially through catecholamine-induced changes in the open probability of ENaC channels. The onset of air breathing, associated with increased intrathoracic negative pressure, assists in the clearance of residual fetal lung fluid into the loose interstitial tissues surrounding alveoli. Fluid is then reabsorbed via lymphatics and pulmonary blood vessels. It is generally accepted that the amount of residual liquid in the lung after transition is complete is approximately 0.37 mL/kg body weight.

Cyclic Stretch: Fetal Breathing Movements

Fetal breathing, detectable as early as 10 weeks of gestation in the human fetus, is an essential stimulus for lung growth (Kitterman, 1996). Fetal breathing occurs for 10%–20% of the time at 24–28 weeks, increasing to 30%–40% after 30 weeks of gestation.

TABLE 42.2 Composition of Human Fetal Lung Fluid Compared With Other Body Fluids

| Component | Lung Fluid | Interstitial Fluid | Plasma | Amniotic Fluid |
|---------------------|------------|--------------------|--------|----------------|
| Sodium (mEq/L) | 150 | 147 | 150 | 113 |
| Potassium (mEq/L) | 6.3 | 4.8 | 4.8 | 7.6 |
| Chloride (mEq/L) | 157 | 107 | 107 | 87 |
| Bicarbonate (mEq/L) | 3 | 25 | 24 | 19 |
| pH | 6.27 | 7.31 | 7.34 | 7.02 |
| Protein (g/dL) | 0.03 | 3.27 | 4.09 | 0.10 |

Originating from the diaphragm, fetal breathing is erratic in frequency and amplitude and changes throughout gestation. The volume of fluid moved is small and insufficient to be cleared from the trachea. Respiratory rates range from 30 to 70 breaths per minute, while periods of apnea of up to 2 hours have been recorded. Sustained periods of fetal breathing increase in duration with advancing gestation. The frequency of fetal breathing varies with sleep state (inhibited during quiet sleep) and exhibits diurnal variation, with the lowest rates recorded early in the morning. Fetal breathing is hormonally responsive, and the inhibition of fetal breathing with the onset of labor is attributed to the action of increased levels of circulating prostaglandins. Maternal medications can influence the frequency of fetal breathing movements. Central nervous system stimulants are associated with increased fetal breathing (i.e., caffeine, amphetamines), whereas depressants are associated with decreased fetal breathing (i.e., anesthetics, narcotics, nicotine, ethanol). Animal studies have clearly shown that permanent cessation of fetal breathing, regardless of the cause, is associated with impaired fetal lung growth. However, the impact on fetal lung development of short-term alterations in fetal breathing frequency and amplitude is unknown. Together, constant distending pressure from the production and retention of fetal lung fluid and episodic cyclic fetal breathing are important mechanisms for lung growth during fetal life.

Alveolarization

While branching morphogenesis is the primary developmental program that establishes the conducting airways of the lung, it is important to remember that alveolarization is the developmental program that will establish the large surface area involved in gas exchange (Galambos and Demello, 2008). This process will result in a 20-fold increase in surface area between birth (with between 0 and 50 million alveoli) and adulthood (>300 million alveoli). Primitive saccules develop low ridges (primary septa) that subdivide the saccule into an alveolar duct containing primary alveoli and outpouchings between the ridges (secondary septa/crests) that establish secondary alveoli (Fig. 42.3). Myofibroblasts and endothelial cells seed the base of developing ridges that will subdivide alveoli, while elastin localizes to the protruding edges of these developing ridges (Branchfield et al., 2016). Septation is critical for the process of microvascular maturation and also leads to the development of the pores of Kohn, allowing gaseous continuity between acini and a route for macrophages to move freely between alveoli.

The topic of alveolarization is rapidly evolving, receiving increasing attention because of observations that infants who die after severe BPD exhibit alveolar simplification with little evidence of secondary septation. It remains unclear to what extent the alveolarization potential may be permanently altered by preterm birth alone—in the absence of other injuries—and whether the developmental program can be resumed after preterm birth.

Interdependence of Alveolar and Vascular Development

Recent evidence suggests that the pulmonary capillary bed actively promotes normal alveolar development, maintains alveolar structures throughout life, and can contribute to degenerative lung disease in adulthood (Peng and Morrissey, 2013). The observation that combined abnormalities in the airways and vasculature occur in BPD supports this hypothesis. Intra-acinar arteries and

veins continue to develop after birth by angiogenesis as long as alveoli continue to increase in number and size. This may well be a reciprocal process because vascular growth around the distal air spaces suggests an inductive influence from the alveolar epithelial cells as well.

Molecular Basis for Lung Development

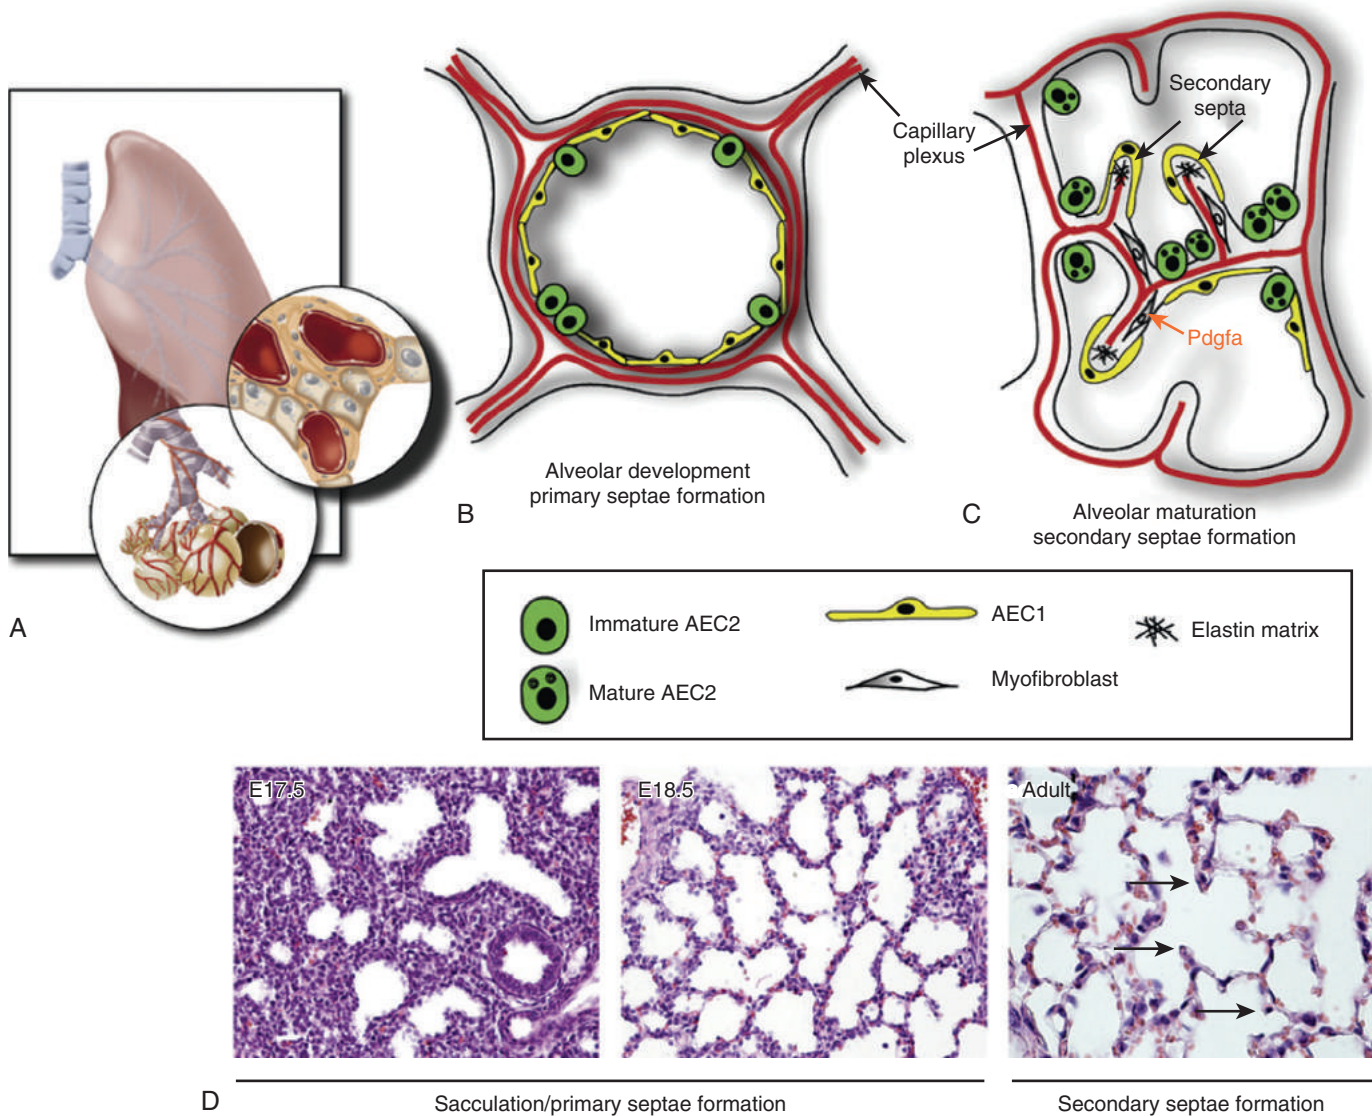

The developmental processes that contribute to lung organogenesis are under the regulation of interdependent signaling pathways mediated by secreted growth factors that are themselves under the control of large networks of transcription factors controlling gene expression. Gene regulatory networks common to other organs that depend on branching morphogenesis for organogenesis, most notably in the kidney and mammary gland, are also found in the lung. Selected regulatory networks are highlighted in the following sections. For more detailed discussion, interested readers are referred to Morrissey and Hogan (2010), Hines and Sun (2014), and Swarr and Morrissey (2015).

Growth Factors in Lung Development

The initiation of branching morphogenesis is the result of the interplay of signals between the developing lung epithelial tube and its surrounding mesenchyme. Central to this process is the family of fibroblast growth factors (FGFs) that are produced and secreted by mesenchymal cells and bind to receptors on the plasma membrane of epithelial cells, setting up a system of mesenchymal–epithelial cross talk. In particular, FGF10, secreted by mesenchymal cells, binds to its receptor, FGF receptor 2 isoform IIIb (FGFR2IIIb), on nearby epithelial cells. This signal is strongest in the epithelial cells at the tip of branching airways owing to a focused FGF10 gradient within the mesenchyme. Binding of the FGF10 ligand to the FGFR2IIIb receptor results in activation of the mitogen-activated protein kinase (MAPK) pathway within epithelial cells, setting off a cascade of downstream signaling events that regulates cell adhesion, cytoskeleton, and cell polarity, all essential elements of cell migration (Lü et al., 2005). One of the genes induced by FGF10/FGFR2IIIb signaling, *SPRY2*, inhibits the MAPK pathway, resulting in feedback inhibition of further FGF10/FGFR2IIIb signaling. Thus a signal propagated by the mesenchyme has an effect that is tightly regulated within the epithelial cell.

Proper lung development requires exquisitely precise FGF10 signaling. Animals expressing reduced levels of FGF10 develop pulmonary hypoplasia with reduced numbers of large airways (Ramasamy et al., 2007; Abler et al., 2009). Furthermore, increased FGF10 signaling during fetal lung development in mice by intrapulmonary injections of recombinant FGF10 produced cystic structures with epithelial characteristics dependent on the location of the injection: proximally with club cells, distally with alveolar type 2 cells (Gonzaga et al., 2008). Together these data provide strong evidence that FGF10 signaling has diverse responses—from initiation of branching to differentiation of epithelial cells—depending on the temporal and/or spatial context of signaling.

Like branching morphogenesis, lung vascular development is a complex and highly organized process that requires multiple vascular signaling molecules to interact in a specific temporospatial sequence. Vascular endothelial growth factor (VEGF) is a critical growth factor in angiogenesis and vasculogenesis. The expression of the VEGF ligand by epithelial cells and VEGF receptors (VEGFRs) by endothelial cells of the developing human fetal lung reinforces the interdependence of the air space and vascular

• Fig. 42.3 Alveolarization. (A) Alveolar development begins in late gestation as the endothelial plexus becomes tightly associated with the epithelium of the distal saccules. (B) Early alveoli contain several important cell types, including the flattened type 1 alveolar epithelial cells (AEC1) used in gas exchange and the cuboidal type 2 alveolar epithelial cells (AEC2) that make surfactant, which lie close to a double capillary network. (C) Maturation of the alveolar compartment is marked by the generation of secondary septa, which involves the development of alveolar crests, a process dependent on the development of myofibroblasts and the deposition of elastin. (D) Histologic sections stained with hematoxylin and eosin demonstrating the changes in distal lung morphology of the developing mouse lung, with secondary septa denoted by arrows. Pdgfa, platelet derived growth factor subunit A, found in myofibroblasts in mature alveolae. (From Morrissey EE, Hogan BL. Preparing for the first breath: genetic and cellular mechanisms in lung development. *Dev Cell*. 2010;18:8–23.)

development. The expression of VEGF mRNA and protein is localized to the epithelial cells at the distal tips of developing lung branches, and the expression levels increase with time (Hislop, 2005; Galambos and Demello, 2008). VEGF gene expression is induced in epithelial cells by the hypoxic environment of the growing fetal lung through the actions of the oxygen-sensing hypoxia-inducible factor family of transcription factors. From the single VEGF gene, five different VEGF protein isoforms are possible, although VEGFA (VEGF165) is the most studied. Each isoform has different affinities for each of the three VEGFRs (Flt-1/VEGFR1, Flk-1/kinase insert domain receptor/VEGFR2, and Flt-4/VEGFR3). Vascular endothelial cells express primarily VEGFR1 and VEGFR2,

whereas VEGFR3 is expressed on the plasma membrane of the lymphatic endothelium. VEGFRs are expressed on the plasma membrane of endothelial cells surrounding the developing airways from very early in gestation, and expression of VEGFR2 is considered the earliest marker of an endothelial progenitor cell. In vitro and in vivo experiments have shown that VEGFA induces endothelial cell proliferation and migration, both key elements of vascular sprouting, as well as tube formation through interactions with VEGFR2. VEGFR1 appears to have more importance in transforming primitive endothelial tubes into stabler vascular networks, in part by reducing endothelial proliferation through downregulation of VEGF production. The embryonic lethality of

animals with reduced VEGF expression attests to the critical importance of VEGF/VEGFR signaling to vascular development in the fetus, though not limited to the developing pulmonary vasculature.

Transcription Factors in Lung Development

The ligand–receptor interactions important for branching morphogenesis and pulmonary vascular development are in part determined by the actions of transcription factors on facilitating or reducing gene expression. Transcription factors are also critical in the differentiation of the lung epithelium from the most rudimentary lung bud out to the type 1 and type 2 alveolar epithelial cells.

The most important transcription factor in the lung is thyroid transcription factor 1 (TTF-1), a product of the *NKX2-1* gene. TTF-1 is considered a master regulator of lung development, as transgenic mice null for *NKX2-1* exhibit complete absence of lung branching (Kimura et al., 1996). *NKX2-1* plays a prominent role in establishing cell fate proximally to distally along the branching lung epithelium, with expression ultimately becoming more restricted to club cells and alveolar type 2 cells. TTF-1 is critical for the expression of genes that are unique to differentiated epithelium, such as *SCGB1A1* expression in club cells and surfactant proteins in alveolar type 2 cells. DNA binding sites are found in the promoter regions of all four surfactant genes, *SCGB1A1*, and *NKX2-1* itself, setting up a positive feedback loop for sustained TTF-1 expression. TTF-1 function is highly dependent on phosphorylation of critical amino acids, although it remains unclear which kinase is involved in this process (DeFelice et al., 2003). VEGFA expression is reduced in animals unable to phosphorylate TTF-1, providing another important link between epithelial and vascular development. TTF-1 is itself regulated by other transcription factors that bind to the promoter region of the *NKX2-1* gene, specifically hepatocyte nuclear factor 3 β and GATA-binding protein 6. Thus the ability of networks of transcription factors to bind to gene regulatory elements of DNA in a coordinated fashion during fetal lung development enables the temporospatial expression of growth factor networks that foster branching morphogenesis, the process of differentiation that ultimately gives rise to the approximately 40 cell types that constitute the human lung and the coordination of both epithelial and vascular development.

Novel Concepts in Lung Development

Stem/Progenitor Cells in the Lung

The ability of lung epithelium to replace cells damaged by normal aging or injury has become the focus of increasing attention (Herriges and Morrissey, 2014; Hogan et al., 2014). Stem cells are undifferentiated and have an unlimited capacity for self-renewal. Asymmetric divisions allow self-renewal through one daughter cell while enabling the other daughter cell to become more terminally differentiated. Progenitor cells are more committed, and although capable of self-renewal, they exhibit more restricted cell fates. Thus far, experiments combining lineage tracing with animal models of lung injury have identified several epithelial progenitor cell types having the capacity for both self-renewal and replacement of a variety of specialized lung epithelial cells. Basal cells in large airways and submucosal glands, identified by the expression of tumor protein p63/p63 and cytokeratin 5, are able to self-renew and give rise to ciliated and secretory cells. Club cells in smaller

airways, identified by the expression of club cell secretory protein, seem to be a more committed progenitor cell since they are able to self-renew but differentiate only into club cells or ciliated cells. A subset of club cells, termed *bronchoalveolar stem cells* (BASCs), located at the bronchoalveolar duct junction and resistant to certain forms of lung injury, appear to have a role in epithelial repair. BASCs are both club cell secretory protein and SP-C positive and thus have the potential to produce either club cells or alveolar type 2 cells. Also in the smaller airways, neuroendocrine cells can self-renew and give rise to club cells and ciliated cells following exposure to injury. The most limited lung epithelial progenitor cell is the alveolar type 2 cell, which divides rapidly to reestablish epithelial continuity in damaged alveoli and then transdifferentiates into alveolar type 1 cells. Less well studied are the mesenchymal progenitor cells that provide vascular and muscular components of the developing lung. Candidate cells have been identified that give rise to endothelial cells in the process of vasculogenesis and airway smooth muscle cells along the branching lung epithelial tubes.

Evidence for the existence of stem/progenitor cells in the lung is strong but limited largely to mouse models of lung development and lung repair. Therefore extrapolation to humans should be done with caution, as the murine transition between terminal bronchioles and alveoli is not equivalent to the transition in the human lung. While the capacity for self-renewal is tantalizing, it necessarily means that such cells are at risk of autonomous growth such as cancer. Controversy exists around the potential to harness these populations of cells as a means for correcting abnormalities of lung development (pulmonary hypoplasia), genetic diseases of the lung (cystic fibrosis), and abnormal repair of injured lungs (BPD).

Epithelial to Mesenchymal Transition

Fibrosis often occurs as the result of severe injury to the lung and has historically been a component of the “old BPD.” Emerging evidence suggests that expansion of fibroblast populations in fibrotic lesions is not simply the result of increased proliferation of local fibroblast populations but rather is the result of transformation of epithelial cells into mesenchymal components, a process known as *epithelial–mesenchymal transition* (EMT) (Bartis et al., 2014; Hines and Sun, 2014). EMT is an essential part of gastrulation and the development of cardiac valves. Neural crest cells are the best model system for EMT, since these epithelial cells must lose their local attachments and travel long distances before locating their final niche before differentiating. The evidence is clear that the changes in cell phenotype characteristic of EMT—from sedentary, interconnected epithelial cell expressing epithelial marker proteins to mobile, proliferative mesenchymal cell with expression fibroblast markers and secretion of collagen and other components of extracellular matrix—are under the control of local growth factors. In the lung the most prominent growth factor in EMT associated with pulmonary fibrosis is TGF β , a growth factor that is also essential for normal branching morphogenesis during early lung development.

It remains uncertain whether EMT has a similarly important role in lung development as it does in cardiac development and whether EMT alone is important for the abnormal repair response to lung injury. There is evidence that EMT makes at least a small contribution to lung development. Under the direction of *Shh* signaling, 5% of the embryonic day 14.5 lung mesenchyme in mice is derived from the mesothelium, the epithelial layer surrounding the lung (Que et al., 2008; Dixit et al., 2013).

**TABLE
42.3****Potential Impact of Premature Birth on Lung Development and Maturation**

| Event | Effect of Preterm Birth | Potential Consequences |
|--|---|--|
| Development of conducting airways | Branching: no effect; completed to the level of the respiratory bronchi by 24 weeks Tone: increased secondary to lung disease in part reflecting developmental deficiency of nitric oxide | None Increased airway resistance |
| Alveolarization | Decreased in severe bronchopulmonary dysplasia; may also be compromised by excess glucocorticoids | Reduced lung growth and lung surface area with increased alveolar size; impaired pulmonary function |
| Development of alveolocapillary membrane | Minimal effect: reaches adult diameter by 24 weeks of gestation; glucocorticoids induce precocious thinning | Gas exchange largely dependent on surface area, not alveolocapillary diameter |
| Type 1 cell differentiation | Variable depending on timing of delivery | Gas exchange largely dependent on surface area |
| Type 2 cell differentiation | Variable immaturity and deficient surfactant production depending on timing of delivery; improved with prenatal administration of glucocorticoids | Developmental deficiency of surfactant content and composition results in respiratory distress syndrome. |
| Hydrophobic surfactant proteins (SP-B, SP-C) | Variable effect depending on timing of delivery and other factors such as infection that can impair gene transcription | High alveolar surface tension; respiratory distress syndrome |
| Hydrophilic surfactant proteins (SP-A, SP-D) | Variable effect depending on timing of delivery; both proteins appear relatively late in the third trimester | Compromised host defense: impaired ability to clear microorganisms from airways and/or alveolar space; impaired ability to modulate inflammatory responses |
| Club cell differentiation | Variable effect depending on timing of delivery; these cells appear in the middle of the second trimester, but antioxidant products appear late in the third trimester | Impaired antioxidant and antimicrobial defenses; may contribute to chronic lung disease and pneumonia |
| Mucociliary clearance | Variable effect depending on timing of delivery; goblet cells decrease in number toward term | Increased mucus production may obstruct small airways |
| Development of the pulmonary capillary bed | Variable effects depending on timing of delivery in parallel to alveolar development | Variable degrees of impaired gas exchange commensurate with impaired alveologenesis and any superimposed lung injury; pulmonary hypertension |
| Pulmonary arteries | Variable effects depending on presence and severity of associated lung disease | Pulmonary hypertension associated with chronic lung disease |
| Fetal lung liquid | Fluid loss: variable effects depending on magnitude and duration of fluid loss (i.e., prolonged premature rupture of membranes) as well as timing of delivery Fluid retention: variable effects depending on timing of delivery because hormone surges near term and in labor promote reabsorption before delivery | Pulmonary hypoplasia Transient tachypnea of the newborn |
| Fetal breathing movements | Variable effects depending on timing of delivery but also depending on maternal exposure to substances that reduce fetal breathing movements | Unlikely to have effects in preterm infants unless coexisting conditions severely limit fetal breathing |
| Respiratory drive | Variable depending on timing of delivery | Apnea of prematurity |

SP-A, Surfactant protein A; SP-B, surfactant protein B; SP-C, surfactant protein C; SP-D, surfactant protein D.

EMT has the potential to reduce epithelial populations, resulting in lung destruction, while expanding mesenchymal fibroblast pools and enhancing local matrix deposition that reduces lung elasticity. Many of the models of EMT are derived from lung cancer cell lines or mouse models, limiting their applicability to humans. However, improved understanding of the processes controlling EMT may lead to novel therapies for limiting or reversing pulmonary fibrosis after lung injury. Furthermore, early events in EMT may be particularly important targets of preventive therapy in premature infants given the potential for EMT to contribute to lung destruction, a more common feature of the new BPD.

Epigenetic Regulation of Lung Development and Maturation

Regulation of normal development and the consequences of abnormal development are at the heart of understanding the implications of preterm birth and the development of potential lung protective therapies. The central dogma of DNA to RNA to protein is being challenged by increasing recognition of epigenetic mechanisms—histone modifications, modification of DNA and RNA, silencing RNA, and microRNA (miRNA)—for regulating gene expression. The evidence that miRNAs play an important role in normal fetal lung development is clear (Khoshgoo et al., 2013). MiRNAs are small, noncoding RNAs (generally 19–22 nucleotides in length) found within cells that target genes for RNA degradation or inhibition of protein synthesis. There are more than 500 recognized miRNAs, some of which are particularly enriched in lung cell populations. MiRNAs are generated from a

process that begins in the nucleus. Long primary miRNA is transcribed, processed, and exported from the nucleus, where further cytoplasmic maturation occurs before the mature miRNA is able to interact with regions of messenger RNA, usually in the 3' untranslated region.

Emerging evidence indicates that miRNAs are essential for normal lung development, since targeted deletion of *dicer*, a key enzyme in miRNA processing, results in abnormal airway development and excessive apoptosis in the lungs (Nardiello and Morty, 2016). The miR-17-92 cluster of miRNA is highly expressed in embryonic mouse lung, decreasing into adulthood as lung development progresses. Altered expression of miR-17-92 suggests a primary role for these miRNAs in maintaining E-cadherin expression in airway epithelial cells during branching morphogenesis.

A novel class of noncoding RNAs, the long noncoding RNAs (or lncRNAs), similarly regulate lung development. These large nucleotides (>200 nucleotides in length) are less stable than mRNA, have fewer posttranslational modifications, and play a role in stabilizing chromatin, thereby regulating gene transcription. The expression of several lncRNAs is spatially and temporally correlated with transcription factors critical to lung development (Herriges et al., 2014). The best characterized is *NANCI* (Nkx2.1-associated noncoding intergenic RNA), which regulates neighboring Nkx2.1 expression. Knockdown of *NANCI* in vivo results in lung sacculation and epithelial differentiation defects.

Because of their role in regulating developmental and pathologic processes, noncoding RNAs are increasingly seen as targets for therapeutic interventions. The obstacles to using miRNA or lncRNA as therapeutic agents are similar to the obstacles encountered in other gene therapies, including mode of delivery, cell and tissue specificity, and the potential for off-target effects.

Summary

Lung branching morphogenesis is coordinated with pulmonary vascular development to provide a large surface area and thin alveolocapillary membrane to accomplish adequate gas exchange in the transition to air breathing and to meet the needs of a growing infant and child. Although occurring late in fetal lung development, maturation of the surfactant system is similarly critical in the transition to air breathing and the maintenance of patency of the gas-exchange surface. Although the fetal lung developmental program requires an array of transcription factors, hormones, and growth factors promoting branching morphogenesis, lung growth is equally dependent on intact neural input to modulate fetal breathing, stability of an appropriately sized thorax, and the presence

of adequate lung and amniotic fluid. Furthermore, the maturation of the host defense and detoxification systems minimizes the effects of increased oxygen tension and exposure to potential pathogens accompanying the transition to air breathing. Premature birth impacts all of these functions, as illustrated in Table 42.3. BPD is the net result of multiple injuries to the underdeveloped lungs of premature newborns that compromise postnatal growth and development, thus impairing function. Integrated approaches to therapy that reflect the interdependency of these lung functions have the most promise for minimizing the impact of premature birth on childhood and, ultimately, adult lung function.

Control of Breathing

ESTELLE B. GAUDA AND RICHARD J. MARTIN

KEY POINTS

- Apnea of prematurity is the manifestation of greater inhibitory (rather than excitatory) influences on the central respiratory network.
- The predominant influence of peripheral arterial chemoreceptors on baseline breathing in premature infants causes periodic breathing and apneas, including postsigh apnea.
- The protective upper airway reflex (laryngeal chemoreflex) prevents aspiration, but in premature infants, profound bradycardia, apnea, and oxygen desaturation can occur—in addition to laryngeal constriction.
- The excessively compliant chest wall in premature infants predisposes to low lung volumes.
- In extremely premature infants, apnea of prematurity can persist beyond 37 weeks' postconceptional age.

How the respiratory network matures is of interest not only to physiologists but also to clinicians who care for infants, newborns, and children with disorders of respiratory control. Neonatologists, in particular, are aware of the challenges of treating infants who are born prematurely. While breathing movements can be detected in the human fetus as early as 10–12 weeks' gestation, the purpose of fetal breathing is not gas exchange but instead the lung stretch that occurs during breathing is essential for lung development. The transition from fetal to neonatal life requires a rapid conversion from intermittent fetal respiratory activity not associated with gas exchange to continuous breathing on which gas exchange is dependent. Breathing in the most premature infants is akin to fetal breathing, which is episodic, punctuated by periods of disturbingly long apneic pauses interspersed with frequent periods of hyperventilation and sighs (augmented breaths). For the infant who is born prematurely, frequent apneas and periods of hypoventilation associated with oxygen desaturations and bradycardia are of significant concern. With maturation, breathing becomes more stable. Thus the premature infant provides a unique opportunity to observe how the respiratory system matures in humans.

Even though breathing is more stable in term infants than in premature infants, the respiratory system at term gestation is still undergoing significant maturation and can become unstable in response to stressors such as infection or hyperthermia. In some term infants who appear well, subtle developmental abnormalities

in the anatomy and neurochemistry of the respiratory system can lead to profound disorders of breathing. Infants who have died of sudden infant death syndrome (SIDS) and those infants with congenital central hypoventilation syndrome (CCHS) or with Rett syndrome have also provided a window of opportunity for careful epidemiologic, genetic, neurochemical, and neuroanatomic studies that have led to a more complete understanding of the genes that regulate the development of the respiratory system and how environmental factors in fetal and early neonatal life may adversely affect normal development of systems that control breathing.

The purpose of this chapter is (1) to present what is currently known about the neuroanatomy, neurocircuitry, and neurochemistry that controls breathing during development and (2) to better understand how infants breathe, why premature infants have apnea of prematurity, why term infants have apnea of infancy, and how genetic errors and environmental exposures modify mechanisms that control breathing during fetal and early neonatal life.

Animal Models of Control of Breathing

Much of our understanding of the basic mechanisms that lead to stable breathing come from studies performed in newborn and adult animals. Earlier studies in newborn pig, dog, and cat as well as the fetal and newborn sheep characterized the developmental physiology, and much has been gained from these models. However, a more detailed understanding of the neuroanatomy, neurocircuitry, and neurochemistry has been obtained with in vitro models from fetal and newborn rats and mice. Of particular relevance, the stage of respiratory development of the rat born at term is similar to that of the human born at 25–29 weeks' gestation. Two different reduced in vitro preparations from rodents have been used to better delineate components of the respiratory network in the brainstem: (1) brainstem slices that include the area that contains the “pacemaker cells mediating rhythmogenesis” and (2) isolated brainstem spinal cord preparations from fetal and newborn rodents. Because the stability and viability of these in vitro preparations are best when tissues are used from the late embryonic stage or within the first week of postnatal life, data from these in vitro preparations are relevant only to respiratory control during very early development. However, these techniques provided the opportunity to carefully characterize the different regions of the brain that are involved in respiration. We now know that the groups of neurons that control the different phases of respiration

have a genetic signature, allowing the use of genetic tools to manipulate the activity of the different regions and observe the physiologic responses in intact animals. Specifically, optogenetics and pharmacologic techniques are often combined to explore the functionality of the specific brain regions related to breathing in unanesthetized adult animals. Thus what we know about how the respiratory network is integrated and functions is based on a significant amount of information obtained from well-designed in vitro and in vivo animal experiments using immunohistochemistry, electrophysiology, fluorescent imaging, genetic manipulation, pharmacology, computational modeling (Richter and Spyer, 2001; Smith et al., 2013) and more recently optogenetics in rodents (Cui et al., 2016; Anderson et al., 2016).

Overview of Respiratory Control

Muscles of Respiration

The diaphragm is the major muscle of respiration, but other muscles of respiration are also essential for unobstructed breathing at rest and augmented breathing during exercise and stress. Thus the muscles of respiration include the pump muscles (diaphragm, intercostal muscles, and abdominal muscles) and muscles of the upper airway (alae nares, pharyngeal muscles, and laryngeal muscles). The diaphragm is innervated by the phrenic nerve, which originates in the spinal column (C3–C5). The upper airway muscles are innervated by motoneurons originating in the brainstem, specifically, the nucleus ambiguus, the dorsal motor nucleus of the vagus, and the hypoglossal nucleus (Nunez-Abades et al., 1992; Jordan, 2001). Different muscles are activated during each of the three phases of the respiratory cycle: inspiration, postinspiration, and expiration. Upper airway muscles are particularly important in modulating the rate of inspiratory and expiratory airflow. During inspiration, the diaphragm, external intercostal muscles (in infants), and posterior cricoarytenoid (laryngeal dilator) contract.

During postinspiration (also known as the *first phase of expiration*), the diaphragm and the thyroarytenoid (laryngeal constrictor) contract. Diaphragmatic and thyroarytenoid postinspiratory activity are common in newborns, both human (Eichenwald et al., 1997) and animal (England et al., 1985). Because the chest wall of newborns, particularly premature newborns, is highly compliant, diaphragmatic and laryngeal postinspiratory activity retards expiration to maintain functional residual capacity. This postinspiratory activity is often audible, known as *grunting*, and is heard in infants with low lung volume disease states, such as surfactant deficiency and atelectasis. Vocalizations, swallowing, and coughing also occur during the postinspiratory phase of respiration (Dutschmann et al., 2014).

The second phase of expiration is often quiescent regarding muscle activity; the diaphragm relaxes and the lungs recoil. However, during exercise and hypercapnia the intercostal and abdominal muscles will contract during the second phase of expiration. Each phase of respiration has a corresponding excitatory region in the brainstem that initiates each phase. While the regions initiating inspiration and forced expiration (second phase of expiration) had been previously identified, the region initiating postinspiratory activity has only recently been localized and validated in rodents (Anderson et al., 2016).

It is essential that the pump muscles, particularly the diaphragm and the upper airway muscles, contract in such a way that unobstructed breathing occurs. There are several disease states in which this is not the case; upper airway obstruction during inspiration

is the hallmark of obstructive sleep apnea that can occur at any age. Premature infants may have an obstructed component of the upper airway from low upper airway tone or active closure of the glottis during apnea.

Respiratory Rhythmogenesis

The motor output of muscles of respiration is a summation of influences on, and intrinsic properties of, respiratory-related neurons in the brainstem. While abnormal breathing can result from disease of the muscle itself, it can also occur from an abnormality anywhere along the cascade, starting from the neurons and cells involved in genesis of respiration and regulation of the respiratory timing to the axons that carry the signal to the motor units. Respiration is a rhythmic motor behavior similar to locomotion that is generated by semiautonomous neural networks known as *central pattern generator*, which are located in the medulla and pons (Smith et al., 2013). Specific brainstem regions contain highly specialized and interconnected neurons that have synchronized activity that results in the three phases of the respiratory cycle (Fig. 43.1). A core group of synaptically coupled excitatory neurons in the brainstem located in the pre-Bötzinger complex (PBC) has pacemaker properties and is the putative site of genesis of inspiratory activity (Smith et al., 1991). These pacemaker neurons express the homeobox gene *DBX1* and are immunopositive for neurokinin 1 (NK1) receptor and somatostatin (Bouvier et al., 2010; Picardo et al., 2013; Wang et al., 2014). The timing of the respiratory cycle is controlled by

• **Fig. 43.1** Simultaneous triple recordings of electric activities of the main populations of respiratory neurons (1), an inspiratory neuron (large spikes, middle tracing); (2), a postinspiratory neuron (small spikes, middle tracing); (3), an expiratory neuron (top tracing) and the phrenic nerve (bottom tracing). Note the augmenting (aug) activity of the phrenic nerve during inspiration and the decrementing (dec) activity of the phrenic nerve during the postinspiratory (PI) phase of the respiratory cycle. The postinspiratory phase is the first phase of expiration (E1) and is associated with phrenic nerve activity. In the second phase of expiration (E2), the phrenic nerve is silent. (Reproduced from Richter DW, Spyer KM. Studying rhythmogenesis of breathing: comparison of in vivo and in vitro models. *Trends Neurosci.* 2001;24:464–472.)

inhibitory interneurons that discharge during specific phases of the respiratory cycle (Smith et al., 1991).

Neuroanatomy of the Central Respiratory Network

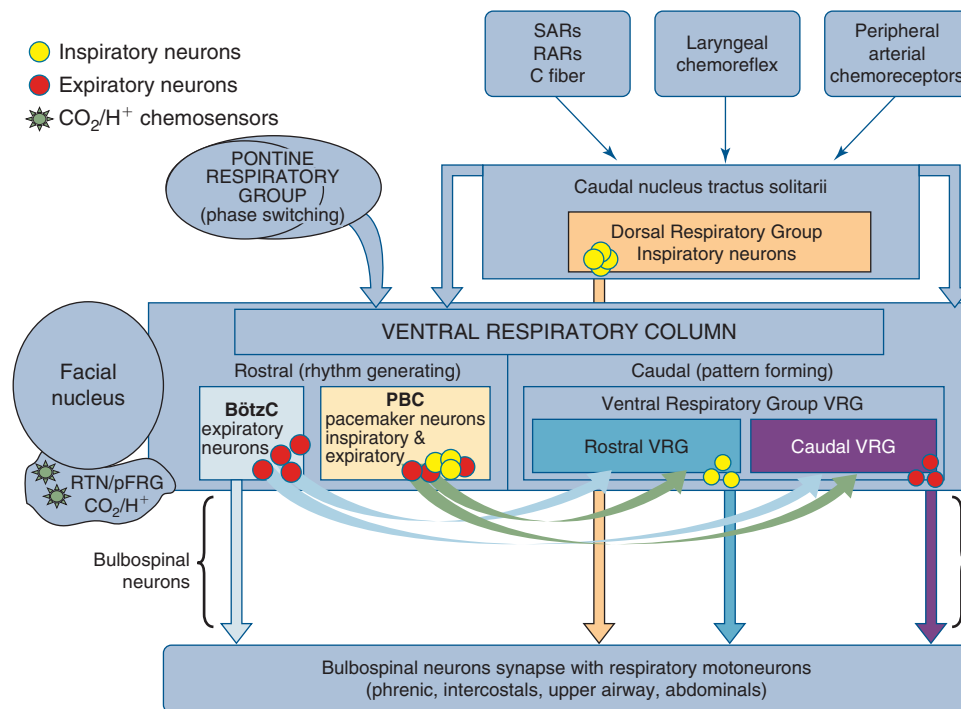

As shown in the anatomic illustration in Fig. 43.2 and the schematic in Fig. 43.3 and summarized in Table 43.1, the respiratory-related neurons are located in three main areas in the brainstem: (1) the dorsal respiratory group within the nucleus tractus solitarius (nTS); (2) the ventral respiratory column (VRC), which extends from the facial nucleus to the ventrolateral medulla at the spinal–medullary junction; and (3) the pontine respiratory group within the dorsolateral pons (Alheid and McCrimmon, 2008; Smith et al., 2013). The VRC can be subdivided into a rostral part, involved in rhythmogenesis, and a caudal part, involved in pattern formation. The VRC should not be confused with the ventral respiratory group (VRG). Bulbospinal neurons are neurons that originate in the medulla (bulbo) and synapse with motoneurons in the spinal column such as the phrenic motoneurons. The rostral VRC contains both the rostral VRG, consisting of a large proportion of bulbospinal inspiratory neurons that project directly to the phrenic and external intercostal motoneurons, and the caudal VRG, containing bulbo-spinal expiratory neurons that project to abdominal and internal intercostal motoneurons. Propriobulbar neurons are neurons originating in the brainstem that send projections to other neurons in the brainstem.

Within the rostral VRC are two areas that are essential to the formation of respiratory rhythm: the PBC and the Bötzinger complex. As outlined already, the PBC contains a core group of synaptically coupled excitatory neurons that have pacemaker properties, similar to the pacemaker cells in the atrioventricular node of the heart. These pacemaker cells are rostral to the nucleus ambiguus, have both intrinsic inspiratory and expiratory bursting properties, and are essential to maintaining respiratory rhythm (Smith et al., 1991). Progressive destruction of the PBC disrupts rhythmogenesis, leading to death in animals (Ramirez et al., 1998). Using immunocytochemistry to identify NK1 and somatostatin positive neurons and anatomical approaches, a similar area has been identified in the human brain. In individuals who had died of neurodegenerative disease with central respiratory deficits, reduced numbers of neurons were identified in the area of the putative PBC as compared with the brains of individuals with neurodegenerative disease without central respiratory deficits (Schwarzacher et al., 2011). The postinspiratory complex (PiCo) is another area, recently discovered, with autonomous rhythm-generating properties that controls postinspiratory activity (Anderson et al., 2016). The PiCo is medial to the nucleus ambiguus and caudal to the nucleus of cranial nerve VII. The Bötzinger complex contains propriobulbar expiratory neurons that provide strong inhibitory inputs to inspiratory and expiratory bulbospinal neurons in the VRC.

Another important group of neurons are those within the retrotrapezoid nucleus (RTN) located along the ventral medullary surface beneath the facial nucleus (see Fig. 43.3). These neurons

• **Fig. 43.2** The anatomic relationship between the regions in the human brainstem that constitute the respiratory network. These regions include specialized neurons in the dorsolateral pons (parabrachial and Kölliker–Fuse nuclei), nucleus of the solitary tract, and ventral respiratory column. The ventral respiratory column is organized rostrocaudally extending from the level just below the facial nucleus to the C1 level of cervical cord. The ventral respiratory column consists of the Bötzinger complex, the pre-Bötzinger complex, and the rostral and caudal ventral respiratory groups (VRGs). Vagal motor neurons of the nucleus ambiguus innervate the laryngeal muscles. The medullary raphe, arcuate nucleus, located just underneath the ventral medullary surface, contains neurons that depolarize in response to hypercapnia and hypoxia. The retrotrapezoid nucleus (not shown) is a CO_2/H^+ chemosensor and is located rostrally below the facial nucleus on the ventral medullary surface. (Modified with permission from Benarroch EE. Brainstem respiratory control: substrates of respiratory failure of multiple system atrophy. *Mov Disord.* 2007;22: 155–161.)

• **Fig. 43.3** Pontine–Medullary Brainstem Network Controlling Respiration and Afferent and Efferent Projections. The pontine respiratory group contains two nuclei that send neuronal projections to respiratory-related neurons in the ventral respiratory column (VRC). The pontine respiratory group mediates phase switching between inspiration and expiration. Within the nucleus tractus solitarius (NTS) are the inspiratory neurons of the dorsal respiratory group with projections to motoneurons in the spinal column. The NTS also receives monosynaptic inputs from vagally mediated reflexes in the lung and upper airways (including slowly adapting receptors [SARs], rapidly adapting receptors [RARs], and C-fiber receptors), laryngeal chemoreceptors, and peripheral arterial chemoreceptors. Projections from second-order neurons in the NTS then synapse with neurons in the rostral VRC and the caudal VRC. The VRC extends from the level of the facial nucleus to C1 in the cervical spinal cord. The rostral VRC is involved in respiratory rhythmogenesis and contains the expiratory neurons of the Bötzinger complex (Bötzc) and the pacemaker cells of the pre-Bötzinger complex (PBC). The Bötzc and PBC contain propriobulbar neurons that project to inspiratory neurons in the rostral ventral respiratory group (VRG) and expiratory neurons in the caudal VRG. The Bötzc also contains bulbospinal neurons that synapse with phrenic motoneurons in the spinal cord, whereas the PBC contains only propriobulbar neurons. Neurons in the VRG are responsible for shaping the respiratory pattern and receive inputs from second-order neurons in the NTS and from rhythm-generating neurons in the Bötzc and PBC. Bulbospinal neurons from the dorsal respiratory group, Bötzc, rostral VRG, and caudal VRG synapse with motoneurons that control the activity of the muscles of respiration. *pFRG*, Parafacial respiratory group; *RTN*, retrotrapezoid nucleus.

have chemosensitive properties and depolarize in response to increasing carbon dioxide (CO_2) concentration and decreasing pH and synapse with rhythm- and pattern-generating neurons in the VRC (Guyenet et al., 2008). All these neuronal groups and networks that contribute to rhythmogenesis are present in newborn animals born at term (e.g., sheep, cats, and pigs) or born prematurely (e.g., rodents) in which rhythmogenesis is well established before birth. Episodic spontaneous fetal breathing movements occur in human fetuses as early as 10 weeks' gestation (de Vries et al., 1985). In rodents, respiratory rhythmogenesis is first detected at embryonic day 15 in rats and embryonic day 17 in mice (Thoby-Brisson and Greer, 2008). The emergence of this respiratory-related activity in rats is coincident with the characteristic expression of NK1 receptors of the PBC (Thoby-Brisson and Greer, 2008).

In summary, respiratory rhythm and inspiratory–expiratory patterns emerge from dynamic interactions between (1) excitatory neuron populations in the PBC and rostral VRG, which are active during inspiration and form the inspiratory motor output, (2)

excitatory neurons in the PiCo, which are active during postinspiration, (3) inhibitory neurons in the PBC that provide inspiratory inhibition within the network, and (4) inhibitory neurons in the Bötzinger complex, which are active during expiration and provide inhibitory inputs to inspiratory and expiratory neurons within the network and to phrenic motor neurons (see Fig. 43.3). Because of the limitations in performing mechanistic experiments in humans, much of what we know about how we breathe is extrapolated from animal models, but many similarities exist between animals and humans regarding the respiratory network. Harper et al. (2014) have described the relationship between damage to specific brain regions observed on brain imaging and specific disorders of respiratory control in humans.

Neurochemical Control of Respiration

Neurotransmitters

Glutamate is the major neurotransmitter mediating excitatory synaptic input to brainstem respiratory neurons and respiratory

**TABLE
43.1****Major Anatomic Regions in the Brainstem Involved in the Pattern and Timing of Respiration**

| Neuroanatomy: Brainstem Respiratory Network | Characteristics | Comment |
|--|---|---|
| Dorsal respiratory group | <ol style="list-style-type: none"> 1. Located in the medulla 2. Receives sensory input from mechanoreceptors and peripheral chemoreceptors 3. Contains primarily inspiratory neurons 4. Synapses with nerves innervating the diaphragm and intercostal muscles | |
| Ventral respiratory group | <ol style="list-style-type: none"> 1. Located in the medulla 2. Contains inspiratory neurons in the rostral ventral respiratory group and expiratory neurons in the caudal ventral respiratory group 3. Sends inspiratory impulses to laryngeal and pharyngeal muscles, diaphragm, and external intercostal muscles 4. Sends expiratory impulses to the abdominal and internal intercostal muscles | Do not confuse the ventral respiratory group with the ventral respiratory column. |
| Pontine respiratory group | <ol style="list-style-type: none"> 1. Includes the Kölliker–Fuse and other parabrachial nuclei 2. Important in timing of inspiration: sends inhibitory signals to the dorsal respiratory group 3. Innervates laryngeal premotor neurons controlling upper airway resistance 4. Innervates spinal projecting neurons controlling phrenic motoneurons | Overstimulation causes apneustic breathing. |
| Retrotrapezoid nucleus (humans)/parafacial respiratory group (rodents) | <ol style="list-style-type: none"> 1. Located in the ventral medulla in the parafacial region 2. Parafacial respiratory group separated into ventral and lateral areas with different effects on respiration 3. Contains glutamatergic neurons expressing the transcription factor paired-like homeobox 2b 4. Express neurokinin 1 receptor 5. Activity regulated by CO₂ or pH 6. Synaptic inputs from peripheral chemoreceptors modify output of this area. 7. Enhances expiratory activity of abdominal muscles during hypercapnia 8. Thought to be insensitive to opioids | <p>Congenital central hypoventilation syndrome</p> <p>Individuals have insensitivity to hypercapnia—retrotrapezoid nucleus is affected.</p> <p>Genetic mutation: polyalanine expansion mutation in the <i>PHOX2B</i> gene</p> |
| Bötzinger complex | <ol style="list-style-type: none"> 1. Located in the medulla 2. Contains expiratory neurons 3. Inhibits inspiratory neurons 4. Involved in controlling the alteration between inspiration and expiration 5. Augments expiratory activity (second phase of expiration) | |
| Pre-Bötzinger complex | <ol style="list-style-type: none"> 1. Located in the medulla 2. Intrinsic rhythmic inspiratory excitatory drive 3. Glutamatergic neurons have widespread projections 4. Also inhibits expiratory neurons during inspiration | |
| Nucleus tractus solitarii | <ol style="list-style-type: none"> 1. Located in the dorsomedial medulla 2. Receives inputs from pulmonary mechanoreceptor, peripheral chemoreceptor, and other visceral sensory afferent inputs 3. The dorsal respiratory group (contains inspiratory neurons) is part of the nucleus tractus solitarii | |
| Brainstem raphe nuclei | <ol style="list-style-type: none"> 1. Located near the midline of the brainstem with extensive rostrocaudal extension from the caudal medulla to the pons 2. Extensive projections throughout the brain and spinal cord 3. Rich source of serotonergic neurons with extensive projections 4. Synapse with neurons that are involved in motor, somatosensory, and limbic systems | Abnormalities in serotonergic neurons in the raphe have been found in infants who died of sudden infant death syndrome. |

TABLE 43.1 Major Anatomic Regions in the Brainstem Involved in the Pattern and Timing of Respiration—cont’d

| Neuroanatomy: Brainstem Respiratory Network | Characteristics | Comment |
|---|--|--|
| Bulbospinal neurons | Neurons originating in the brainstem that synapse with motoneurons in the spinal column | For example, bulbospinal neurons synapse with phrenic motoneurons and with motoneurons for the intercostal muscles |
| Propriobulbar neurons | Neurons originating in the brainstem that send projections to other neurons in the brainstem | For example, the Bötzing complex contains propriobulbar expiratory neurons that provide strong inhibitory inputs to inspiratory and expiratory bulbospinal neurons in the ventral respiratory column |

premotor and motor neurons through binding to α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid kainite receptors (Bonham, 1995) and metabotropic glutamate receptors (Pierrefiche et al., 1994). γ -Aminobutyric acid (GABA) and glycine are the two major inhibitory neurotransmitters mediating inhibitory synaptic input in the respiratory network; they have a key role in pattern generation and termination of inspiratory activity (Haji et al., 2000). GABA (via GABA_A receptors) and glycine (via glycine receptors) mediate fast synaptic inhibition via activation of chloride channels (Bianchi et al., 1995). Throughout development, glutamate always functions as an excitatory neurotransmitter; however, it is not the case that GABA and glycine are always inhibitory neurotransmitters. In early development, GABA and glycine mediate *excitatory neurotransmission* in many neuronal networks, including the respiratory network (Putnam et al., 2005). GABA and glycine signaling modifies the level of chloride in the cell. Activation of the sodium (Na⁺)–potassium (K⁺)–chloride (Cl[−]) cotransporter (NKCC1) and the potassium–chloride transporter (KCC2) on the cell modulates intracellular ion concentrations. Specifically, NKCC1 brings Na⁺, K⁺, and 2Cl[−] into the cell, while activation of KCC2 moves K⁺ and Cl[−] outside the cell. During early development, the high NKCC1/KCC2 ratio causes *high* intracellular chloride concentrations in immature neurons. When GABA then binds to GABA_A receptors, there is net outward movement of Cl[−] ions, leading to membrane depolarization. With maturation, the KCC1/KCC2 ratio reverses, and there is less chloride in the cell. Now when GABA binds to GABA_A receptors, more chloride comes into the cells, leading to hyperpolarization (Rivera et al., 1999; Cellot et al., 2013). With brain injury, NKCC1 expression increases, making the GABAergic system less inhibitory. Moreover, myoclonic jerks are associated with midazolam exposure (GABA_A receptor agonist) in premature infants (Ozcan et al., 2015). GABA_B receptors, which are metabotropic G protein–coupled receptors, also have a greater role in inhibiting respiratory rhythm in adult animals as compared with newborn animals (Kerr and Ong, 1995).

Neuromodulators

The baseline excitatory and inhibitory influences mediated by glutamate and GABA–glycine respectively on major neuronal networks are further altered by many endogenously released neuromodulators that shape and fine-tune respiratory pattern and rhythm throughout development, as outlined in Table 43.2. For example, acetylcholine, substance P, cholecystokinin (CCK), and

thyrotropin-releasing hormone all exert an excitatory drive, whereas opioids, somatostatin, and prostaglandin E₂ exert an inhibitory drive on respiratory-related neurons. Dopamine, adenosine, serotonin, and norepinephrine can have excitatory and inhibitory influences depending on the specific receptors that the neuromodulator binds. Neurons within the PBC that are important in rhythmogenesis are also distinctly identified by being immunopositive for glutamate transporter, NK1, μ -opioid, and GABA_B receptors. Although these cells are primarily excitatory and release glutamate, they can be modulated by synaptic inputs that release substance P, opioids, and GABA (Doi and Ramirez, 2008). These rhythmicogenic neurons produce and are excited by brain-derived neurotrophic factor (Bouvier et al., 2008). Lastly, the presence of μ -opioid receptors and prostaglandin receptors on respiratory-related neurons contribute to the respiratory depression associated with opiate therapy for analgesia and prostaglandin E₁ therapy for congenital heart disease respectively. Similarly, apnea—a common presenting sign of illness in infants—is mediated, in part, by an increase in prostaglandin E₂ levels in the central respiratory network (Hofstetter et al., 2007).

Genetic Mutations Affecting Respiratory Control

Some neuromodulators may be more critical in supporting respiratory rhythmogenesis than others. By identifying the genetic mutations that are associated with marked abnormalities in respiratory control, we can obtain a better understanding of the key role of several neuromodulator systems. For example, serotonergic neurons in the caudal medullary raphe nuclei have extensive projections to phrenic and hypoglossal motoneurons, the nTS, the RTN, and the PBC (Pilowsky et al., 1990). The serotonergic system has a significant influence on the modulation and integration of diverse homeostatic functions, including cardiorespiratory responses and thermogenesis (Kinney et al., 2009). Individuals with Prader–Willi syndrome, who may exhibit breathing abnormalities at birth (Cohen et al., 2014), have mutations in the *necdin* gene (*NDN*) on chromosome 15 leading to abnormalities in the brainstem serotonergic system (Zanella et al., 2008a). Mice lacking the *necdin* gene also have abnormal brainstem serotonergic neurochemistry (Zanella et al., 2008b). Medullary serotonergic neurons are also CO₂ sensitive (Richerson et al., 2001). In genetically modified mice that do not develop medullary serotonergic neurons, CO₂ sensitivity is reduced by 50% (Hodges et al., 2008).

TABLE 43.2**Neurotransmitters and Neuromodulators That Mediate Respiratory Rhythm**

| Neuromodulator | Receptor Subtype | Source of the Endogenous Ligand | Excitatory or Inhibitory on Respiratory Rhythm | Comment |
|----------------|---|--|--|---|
| Glutamate | NMDA, AMPA, GluR | | Excitatory | Major excitatory neurotransmitter |
| Ach | M3 | PAG, LC, X | Excitatory | |
| NE | α 1-Adrenergic | LC | Excitatory | |
| Serotonin | 5-HT _{2A/2B} , 5-HT ₃ , 5-HT ₄ | Raphe | Excitatory | |
| Dopamine | Likely D ₁ | PVN, hypothalamus | Excitatory | |
| ATP | P2X ₂ | Ventral medulla; CO ₂ /H ⁺ -sensitive cells in the RTN | Excitatory | |
| Adenosine | P2Y ₁ | Ventral medulla | Excitatory | |
| Substance P | NK1 | nTS, NA | Excitatory | |
| CCK | CCK1 | nTS, raphe | Excitatory | |
| TRH | TRH-R (1 and 2) | Raphe | Excitatory | |
| GABA | GABA _A , GABA _B | | Inhibitory | Major inhibitory neurotransmitter (can be excitatory during fetal life) |
| Glycine | GlyR | | Inhibitory | Can be excitatory during fetal life |
| NE | α 2-Adrenergic | Pons | Inhibitory | |
| Dopamine | D ₄ | PVN, hypothalamus | | |
| Adenosine | A ₁ , A ₂ | Ubiquitous from metabolism of ATP that increases during hypoxia | Inhibitory | Contributes to respiratory depression at the baseline (A ₁), and mediates HVD |
| Opioid | μ , δ , κ | nTS, PBN, PVN, raphe | Inhibitory | Prominent inhibitory effect during early development |
| PDGF | PDGF- β | nTS | Inhibitory | Contributes to HVD |

Ach, Acetylcholine; AMPA, α -amino-3-hydroxy-5-methyl-4-isoxazolepropionate; ATP, adenosine triphosphate; CCK, cholecystokinin; GABA, γ -aminobutyric acid; GluR, glutamate receptor; GlyR, glycine receptor; HVD, hypoxic ventilatory depression; LC, locus ceruleus; NA, nucleus ambiguus; NE, norepinephrine; NMDA, N-methyl-D-aspartate; nTS, nucleus tractus solitarius; PAG, periaqueductal gray; PBN, parabrachial nucleus; PDGF, platelet-derived growth factor; PVN, paraventricular nucleus; RTN, retrotrapezoid nucleus; TRH, thyrotropin-releasing hormone; TRH-R, thyrotropin-releasing hormone receptor; X, vagal nucleus.

In some infants who have died of SIDS, neuropathologic studies have shown disruptions of the brainstem serotonergic system (Kinney et al., 2009; Paterson et al., 2006b). While specific single-gene mutations that regulate serotonin production and function have not been identified in infants who have died of SIDS, some studies have shown a higher proportion of specific polymorphisms in the 5' regulatory region of the *SLC6A4* gene, which encodes serotonin transporter, which regulates the reuptake of serotonin from the extracellular space. Specifically, infants who have died of SIDS have an increased frequency of the long allele variant and the variable number 12-tandem repeat in intron 2 polymorphisms (Weese-Mayer et al., 2007) in the promoter. The long allele occurs more frequently in African Americans; African Americans also have a 2.7-fold greater incidence of SIDS than whites. Effectively the polymorphisms result in increased activity of serotonin transporter, thereby decreasing the time that serotonin stays in the

synapse, leading to a relative serotonin deficiency causing dysregulation of the cardiorespiratory system.

Rett syndrome is an X-linked disorder with mutations in several genes, but the most common genetic defect (90%) is in the methyl CpG binding protein 2 gene (*MECP2*). Affected individuals are normal at birth and then experience progressive deterioration leading to severe motor, cognitive, and autistic behavioral systems. They also have characteristic severe respiratory disturbances with prolonged apnea and hyperventilation that can be fatal. Genetically modified mice that lack the *MECP2* gene have reduced levels of norepinephrine and serotonin in the medulla and have breathing patterns similar to those of humans with Rett syndrome (Roux et al., 2008). Pharmacologic treatment to increase brain norepinephrine and serotonin levels stabilizes breathing and prolongs the life of these mice (Roux et al., 2007). A case report demonstrating efficacy of fluoxetine and buspirone in reducing breathing

dyregulation in a patient with Rett syndrome has been published (Gokben et al., 2012). Altered GABA neurotransmission might also be causative as suggested by experiments using stem cells from a patient with Rett syndrome that demonstrated that the functional switch of GABA neurotransmission from excitation to inhibition was impaired (Tang et al., 2016).

Congenital central hypoventilation syndrome (CCHS), also known as *Ondine's curse*, is another rare autosomal dominant genetic disorder, occurring in 1 in 200,000 live births. Affected individuals characteristically have adequate ventilation during wakefulness but profound hypoventilation during sleep as well as impaired ventilatory responses to CO₂ and hypoxia during sleep and wakefulness (Berry-Kravis et al., 2006). Although the disorder most commonly presents during infancy, milder forms may present later in childhood or even during adulthood. More than 90% of individuals with CCHS have mutations in the *PHOX2B* gene (Weese-Mayer et al., 1993, 2005; Amiel et al., 2009). *PHOX2B* is a homeobox gene located on chromosome 4 that is specifically expressed in limited types of neurons involved in autonomic processes (Dauger et al., 2003). Its expression is required for the development of the carotid body, nTS, and catecholaminergic neurons. It is also expressed in chemosensitive glutamatergic neurons in the RTN that receive polysynaptic inputs from peripheral arterial chemoreceptors (Guyenet et al., 2008). Thus mutations in the *PHOX2B* gene alter the development of key structures that regulate chemical control of breathing.

The gene has a stretch of 20 alanine repeats in exon 3. Most affected individuals have the classic mutation that adds additional alanine repeats to the 20-alanine repeat, resulting in a stretch of 25–35 alanine repeats instead of 20. This mutation is classified as polyalanine repeat mutations (PARMs). The severity of the disease is correlated with the number of extra alanines. Patients with *PHOX2B*^{20/25} have 25 versus 20 alanines; they have the mildest disease, may never need 24-hour ventilatory support, and may present only after infection or exposure to agents that inhibit respiration. On the other hand, patients with 28–32 alanine repeats in the gene (*PHOX2B*^{20/28–32}) often need continuous ventilatory support. Fewer affected individuals with CCHS have nonpolyalanine repeat mutations (NPARMs) resulting in deletions in exon 3 that cause frameshift mutations. Depending on the mutation, some patients require tracheostomy and long-term ventilation and/or diaphragmatic pacing (Weese-Mayer et al., 2010). While respiratory stimulants are not effective in increasing respiratory drive, drugs that cause respiratory depression may lead to profound respiratory depression (Chen et al., 2006).

From genetically modified mouse models with mutations in the *PHOX2B* gene, we know that its expression is essential for the development of the RTN in the brainstem and catecholaminergic and cholinergic traits in the autonomic nervous system (Moreira et al., 2016). The RTN contains putative central chemoreceptors that have intrinsic pH sensitivity and release the excitatory neurotransmitter glutamate, thereby stimulating breathing during hypercapnia (Holloway et al., 2015). However, abnormalities throughout the autonomic nervous system are often seen in patients with CCHS. Specifically, patients can present with Hirschsprung disease (Haddad syndrome) and neuroblastomas (neuroblastoma–Hirschsprung disease–CCHS syndrome) (Szymońska et al., 2015). As reviewed by Moreira et al. (2016), Hirschsprung disease occurs in 80% of patients with NPARM and 10% of patients with PARM. Similarly, neural crest tumors are found in 1% of PARM patients and in 41% of NPARM patients.

Peripheral Inputs That Modulate the Central Respiratory Network

The nTS in the brainstem (see Fig. 43.3 and Table 43.1) is where sensory information from vagally mediated reflexes and chemical signals from the blood (arterial chemoreceptors) and cerebrospinal fluid (central chemoreceptors) and information from higher brain regions are integrated; neurons from the nTS synapse onto respiratory related neurons, thereby augmenting or attenuating minute ventilation.

Bronchopulmonary Reflexes

Essentially all bronchopulmonary reflexes that modify the depth and duration of inspiration and expiration are mediated through the vagus nerve. The vagus nerve has both myelinated and unmyelinated fibers. Myelinated vagal afferent fibers are activated via (1) slowly adapting stretch receptors (SARs), which are activated by volume and stretch of the lung (mediating the Breuer–Hering reflex), or (2) rapidly adapting receptors (RARs), which are activated in response to inhaled irritants (e.g., ammonia, cigarette smoke) and large inflations or deflations of the lung (Kubin et al., 2006). Activation of SARs changes the duration of inspiration and expiration, whereas activation of RARs causes sighs (i.e., augmented breaths) and cough. Unmyelinated vagal afferents, specifically C-fibers in the airway, are activated by a multitude of chemical stimuli, including CO₂ and capsaicin, in addition to lung edema and elevated temperature. Activation of C-fibers in the lung causes rapid shallow breathing and apnea. Table 43.3 lists bronchopulmonary and upper airway reflexes and their physiologic responses. How these reflexes modify breathing during development is discussed next.

Slowly Adapting Stretch Receptors: Major Modulators of Respiratory Timing

The duration of inspiratory or expiratory effort is greatly influenced by mechanoreceptors that are activated by changes in lung volume. The most well-characterized vagally mediated bronchopulmonary reflex is the pulmonary stretch reflex mediated through SARs, discovered by Josef Breuer in 1868. In adult cats, Breuer showed that expansion of the lungs reflexively inhibits inspiration and promotes expiration and that deflation of the lungs promotes inspiration and inhibits expiration (Widdicombe, 2006). In humans the contribution of the Breuer–Hering reflex to tidal breathing is determined by occlusion of the airway at the end of expiration. The following occluded inspiratory effort is prolonged, and expiratory effort is shortened. Alternatively, the occlusion can be performed at end of an inspiratory effort; then the following occluded expiratory effort is prolonged and inspiratory effort is shortened (Gauda et al., 1987). With this technique, the Breuer–Hering reflex significantly contributes to tidal breathing in infants. The reflex is strongest at birth and then decreases during the first year of life (Rabbette et al., 1994). It is reasoned that the strength of the Breuer–Hering reflex is inversely related to gestational and postnatal age because of the excessively compliant chest wall in newborns, which collapses at lung volumes below functional residual capacity. With decreasing lung volumes during expiration, the Breuer–Hering deflation reflex is activated; the expiratory time is then shorter, and the inspiratory time is longer. Several factors increase the strength of the Breuer–Hering reflex, including premature birth (Kirkpatrick et al., 1976; De Winter et al., 1995), prone sleeping position (Landolfo et al., 2008), active sleep (AS) (Hand et al., 2004), and respiratory distress syndrome (De Winter et al., 1995).

Reflexes from the lungs and airways: historical perspective. *J Appl Physiol* (1985). 2006;101:628–634.

Rapidly Adapting Receptors: Cough, Augmented Breaths

Lung deflation, mechanical stimulation, and chemical irritants also stimulate vagal afferents of RARs, causing augmented breaths, cough, and increased mucus production (Widdicombe, 2006). RARs are also activated at low lung volumes. Newborns, especially premature newborns, have excessive compliance of the chest wall predisposing to low lung volumes during tidal breathing. Activation of RARs and the resulting augmented breath are particularly important in restoring lung inflation in premature and term infants. The frequency of augmented breaths is inversely related to gestational age, with premature infants having the greatest frequency (Alvarez et al., 1993) when compared with term infants and adults. Moreover, augmented breaths in infants have a biphasic pattern with two large inspiratory efforts in succession, whereas in adults only one large inspiratory effort is seen. Augmented breaths in preterm and term infants are also relatively larger than those in adults; immediately after the augmented breath, preterm and term infants often hypoventilate or have apnea because partial pressure of arterial oxygen (PaO_2) rapidly increases and partial pressure of carbon dioxide (PaCO_2) rapidly decreases. These gas changes reduce excitation from peripheral arterial chemoreceptors, leading to

hypoventilation or apnea in infants. In contrast, ventilation often increases after the augmented breath in adults (Qureshi et al., 2009). Peripheral arterial chemoreceptors are also key in inducing augmented breaths (Matsumoto et al., 1997). As a result, the increased activity of RARs during lung deflation and the increased sensitivity of peripheral arterial chemoreceptors in early development contribute to the increased frequency of augmented breaths, postsigh apnea, and ventilatory instability in premature infants.

C-Fiber Receptors: Apnea, Bronchoconstriction, Rapid Shallow Breathing

Pulmonary and bronchial C-fiber receptors are unmyelinated vagal fibers located throughout the respiratory tract, extending from the nose to the lung parenchyma. Pulmonary C-fibers are accessible from the pulmonary circulation, whereas bronchial C-fibers are accessible from the bronchial circulation and have similar sensitivity to various stimuli (Coleridge and Coleridge, 1984). C-fibers are activated by a variety of substances: inflammatory mediators, capsaicin, lobeline, and phenylbiguanidine. Capsaicin and phenylbiguanidine are used experimentally to identify vagal afferents as C-fibers and characterize stimulus–response profiles. C-fiber

simulation induces central and local effects—cough, apnea, laryngospasm, and bronchoconstriction—followed by rapid shallow breathing, bradycardia, and hypotension. Juxtacapillary receptors (J receptors) are composed of C-fibers located in the alveolar walls. They are activated by lung edema and congestion and cause rapid shallow breathing. By far the most common respiratory response from C-fiber stimulation is reflex apnea characterized by prolongation of the expiratory time from excitation of postinspiratory neurons and continuous firing of central expiratory neurons (Coleridge and Coleridge, 1984).

In newborns the stimulation of pulmonary C-fibers by chemical stimulants causes bronchoconstriction and apnea (Frappell and MacFarlane, 2005). Capsaicin-induced apneic response and the sensitivity of the reflex were greatest in newborn rat pups younger than 10 postnatal days (Wang and Xu, 2006). Bronchopulmonary C-fibers are also stimulated by acidosis, adenosine, reactive oxygen species, hyperosmotic solutions, and lung edema. Furthermore, inflammatory mediators in the local environment sensitize C fibers to other stimuli (Lee and Pisarri, 2001).

Pulmonary C-fiber-mediated respiratory inhibition may cause persistent apnea beyond term gestation in infants born at the limit of viability who have lung inflammation from chronic lung disease (Eichenwald et al., 1997). Local C-fiber activation in the lung may also be the mechanism accounting for the increase in apnea observed in infants with viral infections (Pickens et al., 1989) and unlikely to be from direct viral invasion of the central nervous system (Erez et al., 2014). Prenatal exposure to nicotine/tobacco smoke is a known risk factor for SIDS. In newborn rat pups, prenatal nicotine exposure sensitizes bronchopulmonary C fibers and prolongs apnea in responses to C-fiber stimulation. As outlined already, C-fibers are also activated by inflammation (Zhao et al., 2016). The epidemiologic association between infection, prenatal tobacco smoke exposure, and SIDS could be attributed to sensitization of bronchopulmonary C-fibers from tobacco smoke exposure, confounded by acute infection leading to prolonged apnea from which the infant does not recover.

Laryngeal Reflexes

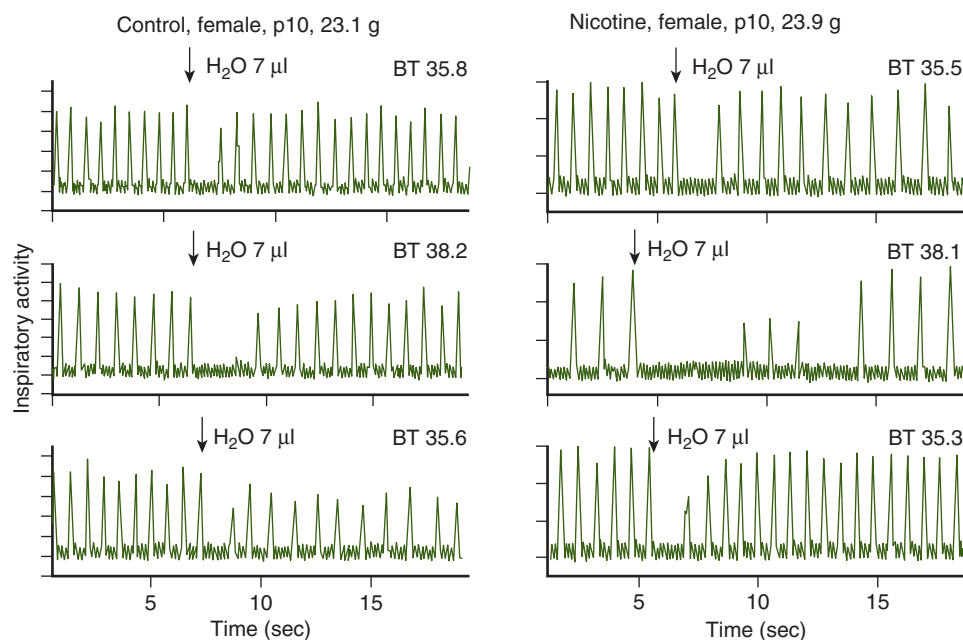

Receptors that respond to changes in upper airway pressure and chemicals are abundantly distributed throughout the laryngeal mucosa. These receptors can be slowly adapting, rapidly adapting irritant receptors, or C-fibers. Water receptors that are stimulated by hypoosmolality and low chloride content may also be involved. Stimulation of upper airway mechanoreceptors and chemoreceptors modifies the activity of upper airway muscles as well as the pattern and timing of diaphragmatic activity. The upper airway reflex that mediates significant cardiorespiratory effects that occur in newborns is the laryngeal chemoreflex (LCR). The LCR is one of the most potent defensive reflexes protecting the respiratory tract from inadvertent aspiration (Harding et al., 1978). Laryngeal chemoreceptors are stimulated by liquid in the airway, which induces coughing, swallowing, and arousal in mature models. However, the response in immature models is apnea followed by hypoventilation, laryngeal constriction, and swallowing (Thach, 2001). In addition to respiratory inhibition, bradycardia, peripheral vasoconstriction, and redistribution of blood flow also occur. The associated apnea and bradycardia can be life threatening in newborns (Sasaki et al., 1977; Boggs and Bartlett, 1982; Wetmore, 1993; Thach, 2001), and in newborns baseline hypoxemia enhances the severity of the apnea and bradycardia induced by the LCR (Wennergren et al., 1989). Afferent fibers for this reflex travel in the superior laryngeal

nerve, a branch of the vagus nerve. These afferents synapse with neurons in the nTS, which then send (1) excitatory projections to motoneurons of the recurrent laryngeal nerve in the nucleus ambiguus, causing constriction of the thyroarytenoid muscle (laryngeal constrictor), resulting in laryngospasm; (2) inhibitory projections to phrenic motoneurons in the cervical spinal cord, inhibiting diaphragmatic contraction, resulting in apnea; and (3) an excitatory pathway to cardiac vagal neurons in the nucleus ambiguus, causing bradycardia. The LCR occurs in the fetus and likely functions to prevent aspiration of amniotic fluid, which contains approximately half the chloride content of pulmonary fluid (Bland, 1990; Reix et al., 2007). In premature infants the reflex may be involved in the apnea and bradycardic responses associated with feeds and gastroesophageal reflux (GER) that reaches the larynx or nasopharynx. Whether the immature response is still present in term infants or how the maturation of the reflex is affected by premature birth has not been determined. Studies in newborn animals show that the apnea associated with the LCR is prolonged during hyperthermia in newborn rats (Xia et al., 2008) and is further accentuated if the animal was exposed prenatally to nicotine (Xia et al., 2010). This relationship is illustrated in Fig. 43.4. Because of profound inhibitory cardiorespiratory effects that are further accentuated by prenatal nicotine exposure, stimulation of the LCR may be an important reflex that is operative in some SIDS cases and infants with acute life-threatening events (Duke et al., 2001; Thach, 2001; Richardson and Adams, 2005; Gauda et al., 2007). Overheating and prenatal exposure to nicotine are both risk factors highly associated with SIDS (Kinney et al., 2009).

Chemical Control of Breathing

Central Chemosensitivity

In air-breathing animals, respiratory rhythmogenesis is primarily driven by the level of PaCO_2 in the blood and cerebrospinal fluid and, to a lesser extent, by oxygen tension. For every 1-mmHg increase in PaCO_2 , ventilation will increase by 20%–30%. Specialized chemosensitive cells in the brainstem depolarize in response to changes in CO_2/H^+ concentration; they drive breathing through synaptic inputs to respiratory-related neurons (Spyer and Gourine, 2009). Although peripheral arterial chemoreceptors in the carotid body also depolarize in response to increasing CO_2/H^+ concentration, these receptors are primarily responsible for modifying breathing in response to changes in oxygen tension (reviewed later). As a result of careful anatomic, physiologic, neurochemical, and genetic studies, the location and the development of central chemoreceptors and some of the genetic factors that drive the development of these receptors in health and disease have been determined. Several groups of neurons in the brainstem, specifically in the medullary raphe, RTN, nTS, locus ceruleus, and fastigial nucleus, are responsive to CO_2/H^+ in vitro and in vivo; therefore they are characterized as chemosensitive. Chemosensitive regions of the brain are identified by the following properties: (1) focal acidification either with acetazolamide (inhibits carbonic anhydrase) or local elevations of CO_2 concentration increase ventilation in adult animals; (2) focal ablation or disruption of the region inhibits the ventilatory response (Feldman et al., 2003). Although several regions are CO_2/H^+ sensitive, there appears to be some specificity in the contribution of each of the regions to chemical control of breathing during wakefulness and sleep (Feldman et al., 2003). The greatest density of CO_2/H^+ sensitive neurons in the brainstem is in serotonergic cells of the raphe of the caudal medulla and

• **Fig. 43.4** Prenatal Exposure to Nicotine and Increased Body Temperature Prolongs the Laryngeal Chemoreflex in Rat Pups at Postnatal Day 10. Example of laryngeal chemoreflex from female postnatal day 10 rat pups during baseline conditions (*top panels*), during mild hyperthermia (*middle panels*), and during a final, recovery period (*bottom panels*). The data displayed on the *left* were obtained from a rat pup born to a control dam, and the data displayed on the *right* were obtained from a rat pup born to a dam infused with nicotine during pregnancy. The *downward arrows* indicate the time at which small volumes of water were injected into the larynx, and the body temperature (BT) is listed to the right of each example. Note the prolonged apnea and respiratory disruption during hyperthermia compared with normothermic conditions, and note that maternal exposure to nicotine markedly prolonged the laryngeal chemoreflex in the rat pup shown on the right. (From Xia L, Leiter JC, Bartlett Jr D. Gestational nicotine exposure exaggerates hypothermic enhancement of laryngeal chemoreflex in rat pups. *Respir Physiol Neurobiol.* 2010;171:17–21.)

glutamatergic neurons of the RTN, located just below the ventral medullary surface (see [Table 43.1](#)). The serotonergic neurons in the caudal raphe project to phrenic motoneurons, where they modulate neuronal plasticity in response to hypoxia ([Feldman et al., 2003](#)). The RTN receives polysynaptic excitatory inputs from peripheral arterial chemoreceptors ([Takakura et al., 2006](#)) and sends projections to neurons in the VRC, including the PBC ([Guyenet et al., 2008](#)). In animals older than seven postnatal days, the activity of the RTN depends on intrinsic pH sensitivity and synaptic drive. RTN neurons detect CO_2 via intrinsic proton receptors (TASK-2, GPR4), synaptic input from peripheral chemoreceptors, and signals from astrocytes ([Guyenet et al., 2015](#)). The parafacial respiratory group may be the precursor to the RTN, and these neurons have intrinsic bursting properties starting at embryonic day 19 ([Guyenet et al., 2008](#)). In humans the arcuate nucleus in the medulla (not to be confused with the arcuate nucleus in the hypothalamus) is believed to be a homologous chemosensitive region similar to that found in animals on the basis of the following findings: (1) the arcuate nucleus is located along the ventral medullary surface; (2) it contains a large population of glutamatergic neurons and a smaller population of serotonergic neurons ([Paterson et al., 2006a](#)); (3) it depolarizes in response to hypercapnia ([Gozal et al., 1994](#)); and (4) the absence of the arcuate nucleus in a human infant was associated with lack of CO_2 sensitivity during life ([Folgering et al., 1979](#)). Purinergic signaling involving the purinergic P2 receptors and adenosine triphosphate (ATP) mediating CO_2/H^+ responsiveness is unique to chemosensitive areas in the RTN

versus that of the raphe or the nTS ([Sobrinho et al., 2014](#)). For an excellent comprehensive review of central chemoreception, see [Guyenet et al. \(2013\)](#).

Maturation of CO_2/H^+ Sensitivity of Central Chemoreceptors

In fetal sheep, hypercapnia causes an increase in the depth of fetal breathing movements, with no change in respiratory rate. In humans, maternal exposure to CO_2 also increases fetal breathing ([Richie and Lakhani, 1980](#)). Ventilatory responses to CO_2 are present immediately after birth in most mammalian species, and CO_2 sensitivity increases with maturation. However, in the newborn rat, CO_2 sensitivity is robust during the first several days of postnatal life; it declines markedly in the next 2 weeks of life and then gradually increases to reach adult levels by the end of the third week ([Stunden et al., 2001](#)). Premature and term infants tested at 2 days of postnatal age have modest ventilatory responses to 2% and 4% CO_2 , although the strength of the ventilatory response is less in the more immature infants ([Frantz et al., 1976](#)). In premature and late preterm newborns, CO_2 sensitivity increases with postnatal age, reaching a mature response by 4 weeks of postnatal age ([Fig. 43.5](#); [Rigatto et al., 1975b, 1975c](#)). Similar to the response in the fetus, the increase in ventilation is predominantly due to an increase in tidal volume and not respiratory rate. If the increase in inspiratory effort against an occluded airway is used as an indicator of central respiratory drive, the increase in CO_2 sensitivity with postnatal development is due to an increase in central

• **Fig. 43.5** The relationship between ventilatory responses to carbon dioxide and gestational age (*top panel*), postnatal age (*middle panel*), and the concentration of inspired oxygen (*bottom panel*). P_{aCO_2} , Partial pressure of carbon dioxide (From Rigatto H, Brady JP, de la Torre Verduzco R. Chemoreceptor reflexes in preterm infants: II. The effect of gestational and postnatal age on the ventilatory response to inhaled carbon dioxide. *Pediatrics*. 1975;55[5]:614–620; and Rigatto H, De La Torre Verduzco R, Gates DB. Effects of O_2 on the ventilatory response to CO_2 in preterm infants. *J Appl Physiol*. 1975;39[6]:896–899.)

respiratory drive in human infants (Frantz et al., 1976). Premature infants with apnea of prematurity have reduced ventilatory responses to CO_2 compared with control infants of the same postconceptional age (Gerhardt and Bancalari, 1984; Durand et al., 1985). This finding suggests that infants with apnea of prematurity have reduced central respiratory drive to breathe when compared with infants who do not have apnea of prematurity at the same postconceptional age.

It is unknown whether maturation of synaptic inputs from chemosensitive neurons to respiratory-related neurons in the brainstem or maturation of intrinsic properties of chemosensitive neurons accounts for the increase in CO_2 sensitivity with early postnatal development. Although such studies of human infants are impossible, data from studies performed in neonatal rats show that intrinsic responses of chemosensitive neurons in the nTS and

locus ceruleus are already mature at birth. It is less clear whether there is a developmental increase in the sensitivity of chemosensitive neurons in the medullary raphe, an increase in the number of chemosensitive neurons in the RTN, or both (Putnam et al., 2005). However, within the first several weeks of postnatal development in the rat, the size of brainstem neurons changes, and both dendritic arborization in the nTS and astrocyte proliferation increase. Astrocytes contribute substantially to the pH of the extracellular milieu surrounding chemosensitive neurons (Putnam et al., 2005). It is likely that all these morphologic and neurochemical changes within and between neurons and astrocytes in the brainstem contribute to maturation of CO_2 sensitivity in the early weeks of postnatal development.

Peripheral Arterial Chemoreceptors

The peripheral arterial chemoreceptors in the carotid body, located at the bifurcation of the carotid artery, are best known for reflex control of ventilation in response to changes in arterial oxygen tension (Nurse, 2014). However, specialized cells within the carotid body also depolarize in response to changes in blood CO_2/H^+ concentration, reflexively increasing ventilation in response to acidosis and hypercapnia and decreasing ventilation in response to hypocapnia. Histologically, the carotid body chemoreceptors consist of (1) type 1 or glomus cells, similar to presynaptic neurons, which are chemosensitive and contain neurotransmitters and autoreceptors; (2) postsynaptic afferent nerve fibers from the carotid sinus nerve, which oppose glomus cells (Gonzalez et al., 1994; Nurse, 2014), contain neurotransmitters and postsynaptic receptors, and have cell bodies in the petrosal ganglion (Gonzalez et al., 1994; Nurse, 2014); (3) type 2 cells, similar to glial cells, which are not chemosensitive; (4) microganglion cells that express cholinergic traits (Gauda et al., 2004); and (5) blood vessels and sympathetic fibers innervating these vessels. In response to hypoxia or increased CO_2/H^+ concentration, type 1 cells depolarize. The major excitatory neurotransmitter in peripheral arterial chemoreceptors is ATP. ATP then binds to the rapid cation ligand-gated ion channel on postsynaptic receptors on the carotid sinus nerve. Neuromodulators, inhibitory and excitatory, further shape the response. For example, dopamine is the most abundant neuromodulator that is produced in and released from the type 1 cells when depolarized. However, dopamine then binds to D_2 receptors on postsynaptic receptors, which leads to inhibition, attenuating ventilatory responses to hypoxia and hypercapnia. Exogenous administered dopamine depresses ventilatory responses to hypoxia and hypercapnia in humans. Adenosine is the breakdown product of ATP, and adenosine A_{2a} and A_1 receptors, which are excitatory and inhibitory G protein-coupled receptors, respectively shape the response of the carotid sinus nerve (Nurse, 2014). Xanthines block both excitatory and inhibitory adenosine receptors.

The commissural nucleus of the nTS is the primary target for afferent processes from peripheral arterial chemoreceptors. Although these afferent processes contain neuromodulators, it is glutamate, binding to both *N*-methyl-D-aspartate (NMDA) and non-NMDA receptors on second-order neurons in the nTS, that is responsible for chemical transmission of excitatory inputs from the peripheral arterial chemoreceptors (Vardhan et al., 1993). These second-order neurons then send tonic excitatory projections to (1) CO_2 -sensitive neurons in the RTN (see earlier) and (2) bulbospinal neurons in the dorsal respiratory group and the VRG that synapse with respiratory motoneurons, leading to changes in the integrated output of the muscles of respiration.

Maturation of CO₂/H⁺ Chemosensitivity of Peripheral Arterial Chemoreceptors

The sensitivity of the peripheral arterial chemoreceptors to CO₂ increases with postnatal development in newborn animals (Carroll et al., 1993); however, in human infants the contribution of peripheral arterial chemoreceptors from central chemoreceptors to ventilatory responses to changes in CO₂ is difficult to delineate. Inferences can be made from the ventilatory response that is seen within a few seconds of exposure to a particular concentration of CO₂, oxygen (O₂), or both because the response time of the peripheral arterial chemoreceptors is faster than that of the central chemoreceptors. What is inferred is that after the first 2 days after birth, peripheral arterial chemoreceptors in newborns are highly responsive to changes in PaCO₂. The postsinh apnea that occurs in infants is the manifestation of this high sensitivity of peripheral arterial chemoreceptors to PaCO₂, which abruptly falls during the sigh (Edwards et al., 2013). In premature infants the PaCO₂ apneic threshold is close to the PaCO₂ that stimulates breathing at rest (Khan et al., 2005). The level of PaCO₂ significantly modifies the sensitivity of the chemoreceptors to the arterial O₂ tension (PaO₂), and this O₂–CO₂ interaction at the carotid body increases with development (Carroll et al., 1993).

Maturation of O₂ Sensitivity of Peripheral Arterial Chemoreceptors

Peripheral arterial chemoreceptors in the carotid body are primarily responsible for changes in ventilation in response to rapid changes in oxygen tension. Changes in ventilation during the first 30 seconds of hypoxia are used to assess the maturation of hypoxic chemosensitivity of the peripheral arterial chemoreceptors, while changes in ventilation in response to hyperoxia measure the contribution of peripheral arterial chemoreceptors on baseline breathing. Hypoxic and hyperoxic sensitivity do not follow the same developmental trajectory. Although oxygen tension less than 25 mmHg stimulates the carotid body in exteriorized fetal sheep, peripheral arterial chemoreceptors are not functional at any level of hypoxia for the first several days after birth in most mammalian species (for a historical overview, see Walker, 1984), including human infants (term and preterm). The rapid increase in arterial oxygen tension during the transition from fetal to neonatal life likely contributes to the resetting of the activation of the carotid body to higher oxygen tension. After birth, hypoxic chemosensitivity gradually increases with postnatal maturation and reaches adult levels by 2–3 weeks postnatally (Rigatto et al., 1975a; Gauda et al., 2009). On the other hand, the contribution of peripheral arterial chemoreceptors to eupneic breathing determined by a drop in ventilation in response to hyperoxia gradually decreases with maturation; the drop in ventilation in response to hyperoxia is greatest in premature versus term infants and least in adults (Al-Matary et al., 2004; Nock et al., 2004). Moreover, premature infants who have a greater frequency of apnea and periodic breathing have a greater reduction in ventilation when exposed to fractional inspired oxygen of 100% (Dejours test). While activity from the peripheral arterial chemoreceptors is not essential for breathing to be established at birth, trophic factors from peripheral arterial chemoreceptors acting on central mechanisms that control breathing during early postnatal development are key in stabilizing rhythmogenesis so that breathing is maintained. The first 2 weeks of postnatal development appear to be the critical period for this trophic influence since sectioning of the carotid sinus nerve (the conduit for trophic support to the central respiratory network) results in death of several mammalian

species from respiratory failure several weeks after denervation (Gauda et al., 2013). Exposures during this critical period of development that can lead to sustained alterations in chemoreceptor function include:

- environmental exposure to the extremes of oxygen tension (chronic or intermittent hypoxia and hyperoxia) (Bavis, 2005; Gauda et al., 2009; Logan et al., 2016)
- nicotine exposure (Gauda et al., 2001; Hafstrom et al., 2005; Stéphan-Blanchard et al., 2013)
- maternal separation—in male rats (Genest et al., 2004)
- perinatal inflammation (Samarasinghe et al., 2015; Master et al., 2016)

Hypoxic Ventilatory Depression: Consequences for the Neonate

Although the peripheral arterial chemoreceptors function to increase ventilation in response to hypoxia, minute ventilation significantly declines after 2–3 minutes of hypoxic exposure. This decline is commonly referred to as *hypoxic roll off*, *hypoxic ventilatory decline*, or *hypoxic ventilatory depression*. Hypoxic ventilatory depression occurs in individuals at all ages, but it is most pronounced in the fetus and newborn (Bissonnette, 2000). Whereas the hypoxic ventilatory decline is usually still above baseline ventilation in mature models, the hypoventilatory response in newborns is usually below baseline ventilation and is often associated with apnea. This hypoxic roll off is not because of a decline in activity of peripheral arterial chemoreceptors. Mechanisms accounting for hypoxic respiratory depression are most well characterized in the fetal animals in which the central brainstem nuclei mediating this response have been attributed to the pons. Transverse section of the upper pons results in a sustained hyperventilatory response to hypoxia in fetal and newborn sheep (Gluckman and Johnston, 1987). Hypoxia activates expiratory neurons in the ventrolateral pons, and chemical blockade of this area blocks the hypoxic respiratory depression in newborn rats (Dick and Coles, 2000).

Several neuromodulators have been implicated in mediating hypoxic ventilatory decline, including norepinephrine, adenosine, GABA, serotonin, opioids, and platelet-derived growth factor, as shown in Table 43.2 (Simakajornboon and Kuptanon, 2005). All these neuromodulators contribute to the ventilatory depression in newborns, but particular attention has been paid to adenosine. Degradation of intracellular and extracellular ATP is the main source of extracellular adenosine, which then mediates its cellular effects by binding to A₁, A_{2a}, A_{2b}, and A₃ adenosine receptors. In response to hypoxia, brain adenosine levels can increase 2.3-fold in fetal sheep (Koos et al., 1994) and 100-fold in rats in response to ischemia (Winn et al., 1981). Nonspecific adenosine receptor blockers, particularly caffeine and methylxanthines, are commonly administered to premature infants to increase central respiratory drive, and aminophylline inhibits hypoxic ventilatory depression in newborns (Darnall, 1985). A₁ adenosine inhibitory receptors are found on respiratory-related neurons (Bissonnette, 2000). Specific A₁ adenosine receptor agonists depress phrenic output in a reduced brainstem spinal cord preparation, whereas A₁ adenosine receptor blockers reverse this inhibitory effect (Dong and Feldman, 1995). In fetal sheep the hypoxic respiratory depression appears to be mediated by excitatory A_{2a} receptors, because blockade of A_{2a} receptors eliminates hypoxic ventilatory roll off in conscious newborn sheep (Koos et al., 1994). Xanthines (e.g., caffeine, aminophylline) block both A₁ and A_{2a} adenosine receptors; therefore their effectiveness in stabilizing ventilation and decreasing the frequency of apnea in premature infants may be by directly

altering the ventilatory response to hypoxia as well as by nonspecifically increasing respiratory drive (see [Apnea of Prematurity](#)).

Effect of Sleep State on Breathing

Sleep state has a profound influence on breathing in the fetus and newborn, and most disorders of breathing that affect the young and old are worse during sleep. AS and quiet sleep (QS) in infants are equivalent to rapid eye movement (REM) and non-REM sleep respectively in older children and adults. Breathing during AS is mostly driven by inputs from the reticular activating system, with less influence from PaCO_2 , whereas breathing during QS is driven by chemical control. Similarly to REM sleep in adults, AS is associated with paralysis of striated muscles. Although this paralysis may be necessary to prevent the acting out of dreams, paralysis of striated muscles that are involved in breathing can be problematic for the newborn. Breathing becomes more irregular in AS and REM sleep because of inhibition of the intercostal muscles and upper airway dilating muscles. The discoordination between chest wall muscles and the diaphragm during AS causes paradoxical breathing: the chest wall moves in during inspiration, with the abdomen moving outward. The more compliant the chest wall, the greater propensity for paradoxical breathing, which is common in the most immature infants. In addition, during inspiration, intrathoracic pressure becomes more negative, and this “suction pressure” causes narrowing or collapse of the compliant upper airway, particularly pharyngeal structures, leading to upper airway obstruction. Paradoxical breathing movements seen on physical examination or detected on inductive plethysmography are often interpreted as a sign of upper airway obstruction. During QS, breathing is characterized by smooth, regular breaths of consistent frequency and depth associated with tonic and phasic activity of the muscles of respiration that are in phase with each other. The chest wall and the abdomen move outward during inspiration, whereas they move inward during expiration. AS and QS can be reliably assessed at 30–32 weeks’ gestation ([Curzi-Dascalova et al., 1993](#)). At this gestational stage, premature infants spend 80% of their sleep time in AS; the proportion decreases to 50% by term, and in adulthood, REM sleep accounts for only 20% of sleep time. Sleep state in normal infants also modifies the time to arousal and the ventilatory responses. The time to arousal on exposure to a hypoxic, somatosensory, or auditory stimulus is greater in AS than with QS in infants during the first 6 months of life ([Horne et al., 2005](#)). The arousal latency in response to a hypoxic stimulus in AS is longer in preterm infants at 2–5 weeks’ postnatal age than that of term infants at the same postnatal age ([Verbeek et al., 2008](#)). The level of oxygen desaturation at the time hypoxic arousal occurs is similar in AS and QS ([Richardson et al., 2007](#)). Respiratory pauses and periodic breathing are more common during AS in both term and premature infants, but the ventilatory response to CO_2 is greater during QS ([Cohen et al., 1991](#)). Because of the complexity of the ventilatory response to hypoxia and the frequent occurrence of arousals induced by hypoxic exposure, assessment of the effect of sleep state on the ventilatory response to hypoxia in newborns is more difficult. Other than the clear difference in arousal in response to a hypoxic stimulus between the two sleep states, differences between sleep states in other respiratory parameters are more variable ([Richardson et al., 2007](#)).

Although most disorders of breathing, such as obstructive sleep apnea, become more severe during sleep, the breathing disorder that is most significantly influenced by sleep state in the newborn is CCHS. As noted previously, CCHS is characterized by

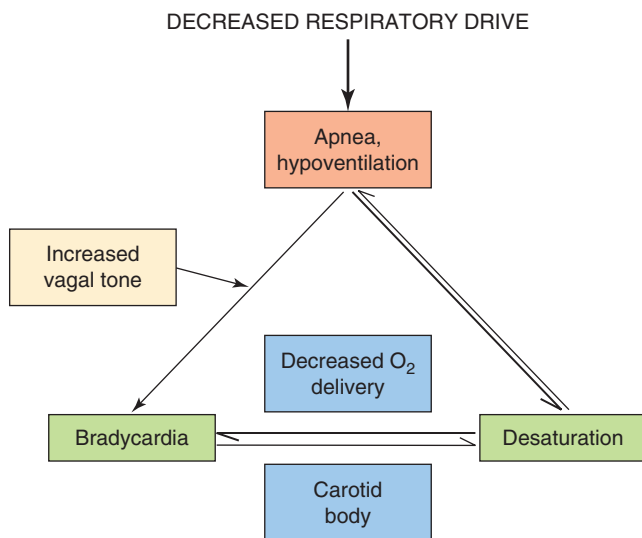

abnormalities in chemical control of breathing; therefore with maturation, as the frequency of QS increases, so does the severity of the disorder. During QS, CO_2 sensitivity is markedly impaired in affected individuals, and exposure to hypercapnia does not significantly increase minute ventilation ([Paton et al., 1989](#)). In infants who died of SIDS, their sleep state during their terminal event is unknown. However, adequate arousal mechanisms are key in preventing respiratory failure and death, and impaired arousal mechanisms are hypothesized to be causative in SIDS. Prone sleeping position increases the percentage of QS ([Horne et al., 2002](#)), and QS is associated with increased time to hypoxic arousal in human infants ([Richardson et al., 2007](#)). A hypoxic microenvironment from rebreathing with defective arousal and autoresuscitative mechanisms is hypothesized to have occurred in infants who have died of SIDS in the face-down (i.e., prone) sleeping position ([Patel et al., 2001](#)). Therefore sleep state can have a significant influence on control of breathing during health and disease, especially in the newborn.

Thus far this chapter has outlined the neurocircuitry and neurochemistry of the respiratory network along with its synaptic inputs that undergo significant maturation during the newborn period. Because these pathways are less developed in premature infants, premature infants have apnea of prematurity, which often requires active therapeutic intervention and can delay hospital discharge. The components of the respiratory network, similarly to other developing organ systems, are plastic and uniquely vulnerable to pathologic processes in premature infants. Therefore the episodes of intermittent hypoxemia and bradycardia that accompany apnea of prematurity may be a cause of acute and chronic morbidities in this high-risk population.

Apnea of Prematurity

Respiratory pauses are universal features in infants born prematurely and are most prominent in the lowest gestational age infants. There is no consensus as to when a respiratory pause can be defined as an apneic episode. It has been proposed that apnea be defined by its duration (e.g., longer than 15 seconds) or accompanying bradycardia and desaturations. However, even the 5-second to 10-second pauses that occur in periodic breathing can be associated with bradycardia or desaturation. It should be emphasized that periodic breathing (ventilatory cycles of 10–15 seconds with pauses of 5–10 seconds) is a normal breathing pattern that should not require therapeutic intervention. It is thought to be the result of dominant peripheral chemoreceptor activity responding to fluctuations in arterial oxygen tension. Episodic bradycardia and desaturation in preterm infants are almost invariably secondary to apnea or hypoventilation ([Fig. 43.6](#); [Martin and Abu-Shaweesh, 2005](#)). The rapidity of the fall in oxygen saturation after a respiratory pause is directly proportional to baseline oxygenation, which is related to lung volume and the severity of lung disease ([Di Fiore et al., 2013](#)). Prenatal and postnatal inflammation directly affect the developing lung and peripheral arterial chemoreceptors ([Masters et al., 2016](#)), which further increases the frequency of oxygen desaturations during short respiratory pauses ([Di Fiore et al., 2013](#); [Fig. 43.7](#)).

Apnea is classified traditionally into three categories on the basis of the absence or presence of upper airway obstruction: central, obstructive, and mixed. Central apnea is characterized by total cessation of inspiratory efforts with no evidence of obstruction. In obstructive apnea, the infant tries to breathe against an obstructed upper airway, resulting in chest wall motion without airflow through the entire apneic episode. Mixed apnea consists of obstructed

• **Fig. 43.6** The sequence of the events whereby apnea results in various combinations of desaturation and bradycardia. (From Martin RJ, Abu-Shaweesh JM. Control of breathing and neonatal apnea. *Biol Neonate*. 2005;87:288–295.)

• **Fig. 43.7** The consequences of the adverse effects of prenatal or postnatal inflammation on the developing lung and respiratory network leading to the emergence of chronic intermittent hypoxia in premature infants. *FRC*, Functional residual capacity. (From Di Fiore JM, Martin JM, Gauda EB. Apnea of prematurity – perfect storm. *Respir Physiol Neurobiol*. 2013;189:213–222.)

respiratory efforts, usually following central pauses. The site of obstruction in the upper airways is primarily in the pharynx, although it also may occur in the larynx and possibly at both sites. It is assumed that there is an initial loss of central respiratory drive, and its recovery is accompanied by a delay in activation of upper airway muscles superimposed on a closed upper airway (Gauda et al., 1987). Mixed apnea typically accounts for more than 50% of long apneic episodes, followed in decreasing frequency by central apnea and obstructive apnea. Purely obstructive spontaneous apnea

in the absence of a positional problem is probably uncommon. Because standard impedance monitoring of respiratory efforts via chest wall motion cannot recognize obstructed respiratory efforts, mixed versus obstructive apnea is frequently identified by the accompanying bradycardia or desaturation (DiFiore et al., 2016a, 2016b).

Presentation of apnea can reflect a nonspecific alteration in either the environment (e.g., thermal) or the general well-being of preterm infants. For example, neonatal sepsis can manifest itself as an increase in the frequency or severity of apnea, and the underlying cause must be treated. Studies using a rat pup model suggest that the systemically released cytokine interleukin-1 β binds to its receptor on vascular endothelial cells at the blood–brain barrier. This binding induces synthesis of prostaglandin E₂, which induces respiratory depression in the brainstem (Hofstetter et al., 2007). These studies provide insight into mechanisms whereby sepsis often manifests itself as apnea of prematurity. Anemia, presumably via decreased oxygen delivery, is also frequently implicated as a cause of apnea. Transfusion of packed red cells can provide some variable benefit for apnea of prematurity (Zagol et al., 2012). Furthermore, there may be some utility in reducing persistent intermittent desaturations in extremely low birth weight newborns younger than 7 days of age (Abu Jawdeh et al., 2014).

Therapeutic Approaches

Continuous Positive Airway Pressure

Continuous positive airway pressure (CPAP) of 4–6 cmH₂O is a relatively safe and effective therapy for apnea of prematurity. Because longer episodes of apnea frequently involve an obstructive component, CPAP appears to be effective by splinting the upper airway with positive pressure and decreasing the risk of pharyngeal or laryngeal obstruction (Miller et al., 1985). CPAP also has beneficial effect in apnea by increasing functional residual capacity, thereby improving oxygenation status. At a higher functional residual capacity, the time from cessation of breathing to desaturation and resultant bradycardia is prolonged. Heated high-flow nasal cannula therapy has been suggested as an equivalent treatment modality to allow CPAP delivery, while improving ease of care. Although this approach is used widely, its efficacy for treatment of apnea of prematurity has not been studied in depth. For example, a recent small study in 10 premature infants with a crossover design suggested that work of breathing may be greater when infants are treated with heated high-flow nasal cannula therapy (HHFNC) versus CPAP therapy (Nasef et al., 2015). Noninvasive ventilatory strategies, using a nasal mask to deliver intermittent positive pressure, avoid the need for full ventilatory support in some infants and can be effective in reducing the need for reintubation for persistent apnea (Lemyre et al., 2014). However, for severe or refractory episodes, endotracheal intubation and mechanical ventilation may be needed. Minimal ventilator settings should be used to allow for spontaneous ventilatory efforts and to minimize the risk of barotrauma.

Methylxanthines

Methylxanthines have been the mainstay of pharmacologic treatment of apnea of prematurity for several decades. Both theophylline and caffeine are used and have multiple physiologic and pharmacologic mechanisms of action. Xanthine therapy appears to increase minute ventilation, improve CO₂ sensitivity, decrease hypoxic depression of breathing, enhance diaphragmatic activity, and decrease periodic breathing. The likely major mechanism of action is through

competitive antagonism of adenosine receptors. Adenosine acts as an inhibitory neuroregulator in the central nervous system via activation of adenosine A_1 receptors (Herlenius et al., 1997). In addition, activation of adenosine A_{2a} receptors appears to excite GABAergic interneurons, and released GABA may contribute to the respiratory inhibition induced by adenosine (Mayer et al., 2006).

Methylxanthines have some well-documented short-term adverse effects. Toxic levels can produce tachycardia, cardiac dysrhythmias, feeding intolerance, and seizures (infrequently), although these effects are seen less commonly with caffeine at the usual therapeutic doses. Mild diuresis is caused by all methylxanthines. The observation that xanthine therapy causes an increase in metabolic rate and oxygen consumption of approximately 20% suggests that caloric demands can be increased with this therapy at a time when nutritional intake is already compromised (Bauer et al., 2001).

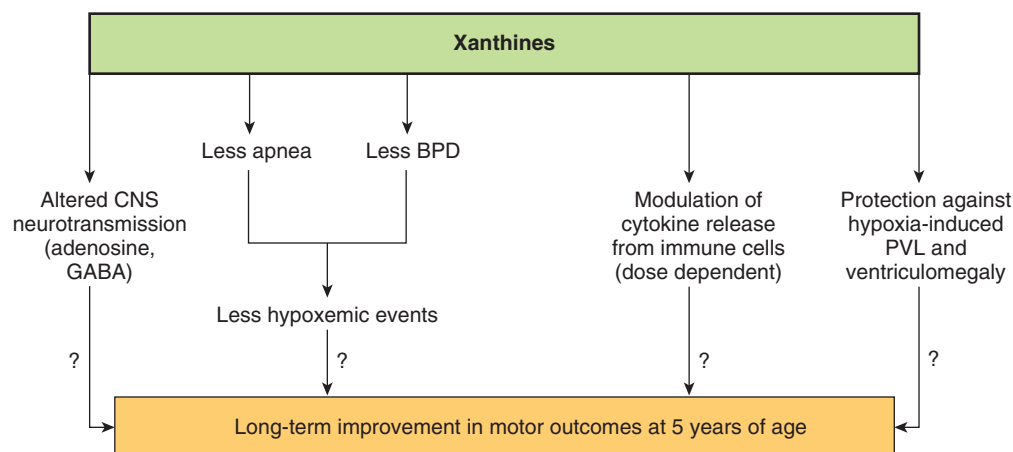

A large, international, multicenter clinical trial was designed to test short-term and long-term safety of caffeine therapy for apnea of prematurity. In the neonatal period, caffeine treatment was associated with a significant reduction in the postmenstrual ages at which both supplemental oxygen and endotracheal intubation were needed (Schmidt et al., 2007). Of even greater interest was the significant decrease in the incidence of cerebral palsy and cognitive delay in the caffeine-treated group, which was not sustained by 5 years of age (Schmidt et al., 2012) but caffeine exposure was associated with a sustained beneficial effect on developmental coordination disorders at 5 years of age (Doyle et al., 2014). This finding raises interesting questions regarding possible mechanisms underlying this beneficial effect of caffeine on neurodevelopmental outcome (Fig. 43.8). These beneficial effects include the observation in animal models that loss of the adenosine A_1 receptor gene is protective against hypoxia-induced loss of brain matter (Back et al., 2006) and a potential benefit of caffeine on immune mechanisms that mediate lung and brain injury (Chavez-Valdez et al., 2009). Recent data in rodent models also support a beneficial anti-inflammatory effect of xanthine therapy in immature lungs exposed to the proinflammatory effects of prenatal exposure to lipopolysaccharide, postnatal

hyperoxia, or both (Köroğlu et al., 2014; Nagatomo et al., 2016). The inhibitory effects of caffeine on adenosine receptor subtypes may differ depending on the xanthine concentrations; this should present a note of caution in the clinical situation when high doses of caffeine are considered. Recent data in an immature ovine model do not, however, demonstrate an adverse effect on developing white matter (Atik et al., 2014).

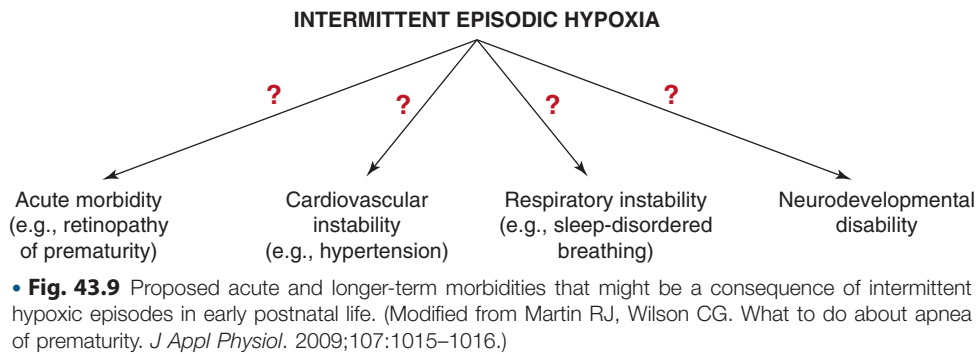

In recent years the practice of caffeine administration has expanded as a result of both increased use of noninvasive ventilation and the success of the earlier caffeine trial. Caffeine is now widely used in a prophylactic mode to prevent, rather than treat, clinically significant apnea; early onset of treatment appears beneficial (Lodha et al., 2015). Extended use beyond apparent resolution of apnea has also been proposed to decrease intermittent hypoxic episodes (Rhein et al., 2014). As already suggested, increased dosing beyond the traditional caffeine citrate loading dose of 20-mg/kg followed by a maintenance dose of 5–10 mg/kg every 24 hours should, however, proceed with caution pending further study. A recent small pilot randomized trial of high-dose caffeine therapy suggested an association between a high loading dose and cerebellar injury on magnetic resonance imaging in preterm infants (McPherson et al., 2015). Although measurement of serum caffeine levels is not widely practiced, these levels may not become subtherapeutic until 11–12 days after cessation of treatment (Doyle et al., 2016). Finally, increased respiratory drive may increase within minutes after intravenous caffeine administration as measured by diaphragmatic activity in preterm infants (Kraaijenga et al., 2015).

Gastroesophageal Reflux and Apnea of Prematurity

GER is often incriminated as a cause of neonatal apnea. Despite the frequent coexistence of apnea and GER in preterm infants, investigations of the timing of reflux in relation to apneic events indicate that they are rarely related temporally. When these events coincide, there is no evidence that GER prolongs the concurrent apnea (Di Fiore et al., 2005). Although physiologic experiments

• **Fig. 43.8** Multiple proposed mechanisms are demonstrated whereby xanthine therapy for apnea of prematurity may improve motor outcomes in former premature infants. These outcomes include functional changes in neurotransmitters in the brain, a decrease in hypoxemic episodes that accompany apnea, especially in the presence of bronchopulmonary dysplasia (BPD), a proposed protective effect of adenosine receptor inhibition on hypoxia-induced white matter injury, and the beneficial effect of adenosine receptor blockade on inflammatory cytokine-mediated lung or brain injury. CNS, Central nervous system; GABA, γ -aminobutyric acid; PVL, periventricular leukomalacia. (Modified from Abu-Shaweesh JM, Martin RJ. Neonatal apnea: what's new? *Pediatr Pulmonol*. 2008;43:937–944.)

in animal models reveal that reflux of gastric contents to the larynx induces reflex apnea, there is no clear evidence that treatment of reflux affects the frequency of apnea in most preterm infants. Therefore pharmacologic management of reflux with agents that decrease gastric acidity or enhance gastrointestinal motility generally should be reserved for preterm infants who exhibit signs of emesis or regurgitation of feedings, regardless of whether apnea is present, and infants at specific risk (e.g., exhibiting neurodevelopmental delay or following gastrointestinal surgical repair). Extreme caution should be taken when histamine H_2 receptor blockers are used to change gastric pH since use of these agents in hospitalized very low birth weight infants has been associated with increased incidence of necrotizing enterocolitis and increased mortality (Romaine et al., 2016). Therapy for such infants should begin with nonpharmacologic approaches, such as thickened feeds, because acid suppression therapy has been shown to alter the gastrointestinal microbiome and increase the risk of lower respiratory infection in infants (Gupta et al., 2013) and necrotizing enterocolitis (Terrin et al., 2012). There remain considerable differences of opinion among neonatologists, pediatric gastroenterologists, and pediatric pulmonologists regarding diagnosis and management of this problem (Golski et al., 2010).

Resolution and Consequences of Neonatal Apnea

Apnea of prematurity generally resolves by 36–40 weeks' postconceptional age; however, apnea frequently persists beyond this time in more immature infants. Available data indicate that cardiorespiratory events in such infants return to the baseline normal level at 43–44 weeks' postconceptional age (Ramanathan et al., 2001). In other words, beyond 43–44 weeks' postconceptional age, the incidence of cardiorespiratory events in preterm infants does not significantly exceed that in term infants. The persistence of cardiorespiratory events may delay hospital discharge for a subset of infants. In these infants, apnea longer than 20 seconds is rare; rather they exhibit frequent bradycardia to less than 70 to 80 beats per minute with short respiratory pauses (Di Fiore et al., 2001). The reason that some infants exhibit marked bradycardia with short pauses is unclear, but available data suggest a vagal phenomenon and benign outcome. For a few of these infants home cardiorespiratory monitoring, until 43–44 weeks' postconceptional age, is offered in the United States as an alternative to a prolonged hospital stay. The apparent lack of a relationship between persistent apnea of prematurity and SIDS has significantly decreased the practice of home monitoring, with no increase in the SIDS rate. Infants born prematurely experience multiple problems during

their time spent in the neonatal intensive care unit, and many of these conditions can contribute to poor neurodevelopmental outcomes. For example, a history of hyperbilirubinemia has been associated with persistent apnea of prematurity in preterm infants and animal models (Amin et al., 2005; Mesner et al., 2008). The problem of correlating apnea with outcome is compounded by the fact that nursing reports of apnea severity may be unreliable, and impedance monitoring techniques will fail to identify mixed and obstructive events. Despite these reservations, available data suggest a link between the number of days of assisted ventilation and the number of days of apnea after extubation with impaired neurodevelopmental outcome (Janvier et al., 2004). A relationship has also been shown between delay in resolution of apnea and bradycardia beyond 36 weeks' corrected age and a higher incidence of unfavorable neurodevelopmental outcome (Pillekamp et al., 2007). Finally, a high number of cardiorespiratory events recorded after discharge via home cardiorespiratory monitoring appear to correlate with less favorable neurodevelopmental outcome (Hunt et al., 2004).

Recent studies have focused more on the incidence and severity of desaturation events, because techniques for long-term collection of pulse oximetry data are now more advanced. Furthermore, it is likely that recurrent hypoxia is the detrimental feature of the breathing abnormalities exhibited by preterm infants. Recent data demonstrate that hypoxic episodes of at least 60 seconds' duration are associated with an unfavorable neonatal outcome in a large cohort of preterm infants (Poets et al., 2015). Fig. 43.9 summarizes proposed morbidities that might be attributable to intermittent hypoxic episodes in early life. Recurrent episodes of desaturation during early life and resultant effects on neuronal plasticity related to peripheral and central respiratory control mechanisms may serve as an important future direction for study.

Neonatal Pulmonary Physiology

THOMAS N. HANSEN, C. PETER RICHARDSON, AND ROBERT M. DIBLASI

KEY POINTS

- Gas flows in and out of the lung only in the presence of pressure gradients. Typically, gas flow ceases at the end of inspiration and the end of expiration if ventilation is uniform.
- Airway resistance varies with the fourth to fifth power of the radius of the airway, making gas flow highly sensitive to changes in airway diameter.
- Measurements of pulmonary function that rely on measurement of expiratory gas flow may not measure flow out of poorly ventilated lung units. This could cause them to underestimate total lung resistance and miss the effect of therapies such as bronchodilator therapies.
- The primary cause of hypoxemia in infants with lung disease is the continued perfusion of open but poorly ventilated lung units. Attempts to correct hypoxemia should be directed at improving oxygenation in these lung units by administration of oxygen or by improving ventilation with continuous positive airway pressure (CPAP) or mechanical ventilation.
- The major pulmonary disability of the premature infant, in the absence of respiratory distress syndrome, is a highly compliant chest wall that can allow lung volumes and PaO_2 to decrease and contribute to apnea. The treatment is to restore lung volume with use of nasal CPAP if possible.
- Pulmonary edema occurs when the rate of fluid filtration exceeds the rate of fluid removal by pulmonary lymphatics.

Lung Mechanics and Lung Volumes

The lungs possess physical, or mechanical, properties that resist inflation, such as elastic recoil, resistance, and inertance. The dynamic interaction between these properties determines the effort that must be exerted during spontaneous breathing and the resting and extreme values for the volume of gas in the lung.

Elastic Recoil

The lung contains elastic tissues that must be stretched for lung inflation to occur. Hooke's law requires that the pressure needed to inflate the lung must be proportional to the volume of inflation (Fig. 44.1). Conventionally, the volume of inflation is plotted on the y -axis, and the distending pressure is plotted on the x -axis. In this way the constant of proportionality is volume divided by pressure, or lung compliance. Throughout the range of *tidal* ventilation the relationship between pressure and volume is linear. At

higher lung volumes, as the lung reaches its elastic limit (i.e., total lung capacity), this relationship plateaus, making the pressure–volume relationship nonlinear.

The lungs and the chest wall function as a unit (the respiratory system) coupled by the interface between the parietal and visceral pleura. Therefore respiratory system compliance (CRS) can be partitioned into lung compliance (CL) and chest wall compliance (CCW), where $1/\text{CRS} = 1/\text{CL} + 1/\text{CCW}$. The tendency for the lung to collapse inward at the end of exhalation is balanced by the outward recoil of the chest wall, resulting in a negative (subatmospheric) intrapleural pressure. The functional residual capacity (FRC) is the volume of gas in the lungs when the elastic forces of the lung and chest wall reach equilibrium (Greenspan et al., 2005). Inflation of the respiratory system above FRC requires a positive distending pressure that must overcome the elastic recoil of both the lung (alveolar pressure minus intrapleural pressure) and the chest wall (intrapleural pressure minus atmospheric pressure) (Gappa et al., 2006). Deflation below FRC requires an active expiratory maneuver. Residual volume (RV) is defined as the volume of air that cannot be expired even with a forced deflation.

As depicted in Fig. 44.1, the relative compliance of the lung of the newborn is similar to that of the adult (Krieger, 1963). However, the infant's chest wall is composed primarily of cartilage, whereas in adults the chest wall is completely ossified and therefore CCW is greater in infants than in adults (see Fig. 44.1), and pleural pressure is only slightly subatmospheric. Measurements of lung and chest wall compliance suggest that the newborn should have a lower percent RV and a lower percent FRC than the adult. In fact, the percent FRC in the newborn is equal to the adult's, and the infant's percent RV is slightly greater. This seeming paradox exists because FRC and RV are measured while the infant is breathing, and predictions from the pressure–volume curves assume that there is no air movement and that there is passive relaxation of all respiratory muscles (Bryan and England, 1984).

Establishment of the FRC is vital to the role of maintaining adequate lung mechanics and gas exchange. The highly compliant newborn chest wall exerts very little outward distending pressure, and thus the lung is more prone to collapse at the end of exhalation (Hülkamp et al., 2005). Data suggest three mechanisms by which the newborn can limit expiratory flow and increase the intrapulmonary pressure to maintain a normal FRC during spontaneous breathing: (1) by increasing expiratory resistance through laryngeal adduction (glottic narrowing), (2) by maintaining inspiratory muscle activity throughout expiration, and (3) by initiating high breathing frequencies to limit the expiratory time (gas trapping) (Magnenat et al., 2004; te Pas et al., 2008).

• **Fig. 44.1** An idealized plot of volume as a function of distending pressure for the lung, chest wall, and respiratory system (lung plus chest wall) of an adult (A) and an infant (B). The curves are derived by instillation or removal of a measured volume of gas from the lung and allowing the respiratory system to come to rest against a shuttered airway. At this point only elastic forces are acting on the respiratory system, and airway pressure is equal to alveolar pressure. Intrapleural pressure can be measured with an esophageal balloon. Because airway pressure is equal to alveolar pressure, the distending pressure for the lung can be measured as *airway pressure minus intrapleural pressure*. The distending pressure for the chest wall is *intrapleural pressure minus atmospheric pressure*, and the distending pressure for the respiratory system is *airway pressure minus atmospheric pressure*. Compliance is the change in volume divided by the change in distending pressure. The shaded area is the resting intrapleural pressure at functional residual capacity (FRC). The lung volumes depicted are residual volume (RV), FRC, and total lung capacity (TLC).

Resistance

Resistance to gas flow arises because of friction between gas molecules and the walls of airways (i.e., airway resistance) and because of friction between the tissues of the lung and the chest wall (i.e., viscous tissue resistance). Airway resistance represents approximately 80% of the total resistance of the respiratory system, and tissue resistance and inertial forces account for the remaining 20% (Polgar and String, 1966). In the newborn, nasal resistance represents nearly half of the total airway resistance; in the adult, it accounts for about 65% of the airway resistance (Polgar and Kong, 1965).

Gas flows only in response to a pressure gradient (Fig. 44.2). During laminar flow the pressure difference needed to move gas through the airway is directly related to the flow rate times a constant (airway resistance). During turbulent flow, however, this pressure is directly proportional to a constant times the flow rate squared. Gas flow becomes turbulent at branch points in airways, at sites of obstruction, and at high flow rates. Turbulence occurs whenever flow increases to a point that the Reynolds number exceeds 2000. This dimensionless number is directly proportional to the volumetric flow rate and gas density, and it is inversely proportional to the radius of the tube and the gas viscosity. Obviously, turbulent flow is most likely to occur in the central airways, where volumetric flow is high, rather than in lung periphery where flow is distributed across a large number of airways. Both types of flow exist in the lung, so the net pressure drop is calculated as follows (Pedley et al., 1977):

(1)

$$\Delta P = (K_1 \times \dot{V}) + (K_2 \times \dot{V}^2).$$

It is possible to take advantage of the differences between laminar and turbulent flow to determine the site of airway obstruction in

• **Fig. 44.2** Gas flow (\dot{V}) through tubular structures occurs only in the presence of a pressure (P) gradient ($P_{in} > P_{out}$). For laminar flow, P is directly proportional to \dot{V} :

$$\Delta P = (\dot{V} \times 8 \times L \times \mu) / (\pi \times r^4).$$

In this case the constant of proportionality (K_1) is directly related to the length of the airway (L) and the viscosity of the gas (μ) and is indirectly proportional to the fourth power of the radius of the airway (r). For turbulent flow, ΔP is proportional to \dot{V}^2 . The constant of proportionality (K_2) is directly proportional to the length of the airway and the density of the gas and inversely proportional to the fifth power of the radius of the airway.

the lung. If obstruction to gas flow is in the central airways, turbulent flow is affected the most. Because turbulent gas flow is density dependent, if the patient breathes a less dense gas (such as helium mixed with oxygen), the resistance to gas flow is reduced. If the site of obstruction is peripheral, the mixture of helium and oxygen does not appreciably affect resistance.

Inflation of the lung increases the length of airways and might therefore be expected to increase airway resistance; however, lung inflation also increases airway diameter. Because airway resistance varies with the fourth to fifth power of the radius of the airway, the effects of changes in airway diameter dominate, and resistance is inversely proportional to lung volume (Rodarte and Rehder, 1986). Airway resistance is lower during inspiration than during expiration because during inspiration, pleural pressure becomes more negative, and a greater distending pressure is applied across the lung. This distending pressure increases airway diameter as well as alveolar diameter and decreases the resistance to gas flow. During expiration, pleural pressure increases and airways are compressed. Collapse of airways is opposed by their cartilaginous support and by the pressure exerted by gas in their lumina. During passive expiration these defenses are sufficient to prevent airway closure. When intrapleural pressure is high, during active expiration, airways may collapse, and gas may be trapped in the lung. This problem may be accentuated in the small preterm infant with poorly supported central airways.

Inertance

Gas and tissues in the respiratory system also resist accelerations in flow. Inertance is a property that is assumed to be negligible during quiet breathing and physiologically significant only at rapid respiratory rates.

Dynamic Interaction

Compliance, resistance, and inertance all interact during spontaneous breathing (Fig. 44.3). This interaction is described by the equation of motion for the respiratory system:

(2)

$$P(t) = (V[t] \times 1/C) + (\dot{V}[t] \times R) + (\ddot{V}[t] \times I),$$

where $P(t)$ is the driving pressure at time t , $V[t]$ is the lung volume above FRC, C is the respiratory system compliance, $\dot{V}[t]$ is the rate of gas flow, R is the resistance of the respiratory system, $\ddot{V}[t]$ is the rate of acceleration of gas in the airways, and I is the inertance of the respiratory system. If I is disregarded, the equation simplifies to

(3)

$$P(t) = (V[t] \times 1/C) + (\dot{V}[t] \times R).$$

At times of zero gas flow (end expiration and end inspiration), the equation further simplifies to

(4)

$$P(t) = (V[t] \times 1/C) \text{ and } C = V(t)/P(t).$$

This series of equations and Fig. 44.3 demonstrate that at points of no gas flow (end of expiration and end of inspiration), only elastic forces are operating on the lung. During inflation or deflation of the lung, however, both elastic and resistive forces are important.

Work of Breathing

The work of breathing (WOB) is a reflection of the amount of energy required to overcome the elastic and resistive elements of the respiratory system and move gas into and out of the lung

• **Fig. 44.3** Gas flows from the atmosphere into the lung only if atmospheric pressure (P_{atm}) is greater than alveolar pressure (P_{alv}). At the end of exhalation, when P_{atm} equals P_{alv} , there is no gas movement in or out of the lung. During a spontaneous inspiration, the diaphragm contracts, the chest wall expands, and the volume in the intrathoracic space increases. As a result, pleural pressure (P_{pl}) decreases relative to P_{atm} , and a gradient is created between P_{pl} and P_{alv} , distending the lung, increasing alveolar volume, and decreasing P_{alv} . A gradient is also created between P_{atm} and P_{alv} , and gas flows from the atmosphere into the alveolar space. The rate of gas flow increases rapidly, reaches a maximum (peak flow), then decreases as the alveolus fills with gas and P_{alv} approaches P_{atm} . At peak inspiration, P_{alv} equals P_{atm} , and lung volume is at its maximum, as is P_{pl} . The curved solid line connecting the end of expiration to the end of inspiration is the total driving pressure for inspiration (P_{tot}). The dotted line represents the pressure needed to overcome elastic forces alone (P_{el}). The difference between the two lines is the pressure dissipated overcoming flow resistive forces (P_{fr}). During exhalation, this cycle is reversed.

during spontaneous breathing. WOB is defined as the cumulative product of distending pressure and the given volume displaced during inhalation or exhalation (Fig. 44.4):

$$WOB = \int P dV,$$

where P is pleural pressure (in time) above resting pleural pressure and V is the volume (in time) relative to the resting thoracic volume (see Fig. 44.4).

The WOB required to ventilate the lungs of normal newborns is approximately 10% of that required in adults (McIlroy and Tomlinson, 1955). However, infants have been shown to have a higher oxygen cost and lower mechanical efficiency associated with the WOB than adults (Thibeault et al., 1966). In healthy infants, most of the WOB is done by the diaphragm during inhalation. Approximately one-third of the total inspiratory WOB is related to overcoming the resistance to gas flow in the airways (Mortala et al., 1982). Exhalation is usually passive because of the potential energy stored in the lung and the chest wall at the end of inhalation but may become active as expiratory resistance increases or lung volumes decrease below FRC.

Measurements of Respiratory System Mechanics

Respiratory system mechanics are objective measurements used to determine the severity of lung disease, changes in pathophysiology,

• **Fig. 44.4** Pressure–volume loop showing the compliance line (AC, joining points of no flow); work done in overcoming elastic resistance (ACEA), which incorporates the frictional resistance encountered during expiration (ACDA); work done in overcoming frictional resistance during inspiration (ABCA); and total work done during the respiratory cycle (ABCEA), or the entire shaded area. FRC, Functional residual capacity; RV, residual volume; TLC, total lung capacity. (From Wood BR. Physiologic principles. In Goldsmith JP, Karotkin EH, eds. *Assisted Ventilation of the Neonate*. 4th ed. Philadelphia: WB Saunders; 2003:15–30.)

response to therapeutic interventions, and progression of lung growth and development. Table 44.1 shows mechanics values for well and sick newborn infants. Lung mechanics in infants are typically measured during spontaneous breathing or during assisted ventilation or during short periods of apnea induced by taking advantage of the Hering–Breuer reflex.

There are a number of methods to calculate resistance and compliance of the respiratory system and their individual components. This section will deal with some of the more commonly used methods (Mammel and Donn, 2015; Peterson-Carmichael et al., 2016).

Resistance of the total respiratory system can be calculated from measurements of driving pressure and the rate of gas flow and can be measured only when the lung is moving. The choice of driving pressure determines the site of the measurement. Most commonly the driving pressure is airway pressure minus atmospheric pressure (resistance of the respiratory system) or airway pressure minus intrapleural pressure (total lung resistance). Gas flow rates are calculated from measurements obtained from devices placed in the infant's airway via a face mask, nasal prongs, or an endotracheal tube. If there are no leaks, all of the gas flow in and out of the infant's lungs will travel through a pneumotachometer, which calculates flow as the pressure drop across a fixed resistance or a hot wire anemometer, which calculates flow by measuring the transfer of heat from a heated wire in the circuit just proximal to the infant.

More recently, investigators have placed elastic bands embedded with coils arranged in a sinusoidal pattern around the chest and

TABLE 44.1 Lung Volumes and Mechanics of Well and Sick Neonates

| Measurements | Units | Normal | RDS | BPD |
|--------------|----------------------------|--------|---------|---------|
| Tidal volume | mL/kg | 5–7 | 4–6 | 4–7 |
| FRC | mL/kg | 25–30 | 20–33 | 20–30 |
| Compliance | mL/cmH ₂ O | 1–2 | 0.3–0.6 | 0.2–0.8 |
| Resistance | cmH ₂ O/L per s | 25–50 | 60–160 | 30–170 |

BPD, Bronchopulmonary dysplasia; FRC, functional residual capacity; RDS, respiratory distress syndrome.

abdomen. As an infant breathes, changes in the rib cage and abdominal cross-sectional areas defined by the bands can be transduced into electric signals (respiratory inductance plethysmography [RIP]). The change in cross-sectional area can be used to estimate the rate of gas flow and if calibrated can be used in the calculation of lung mechanics. In addition, with calibration the resting values can be used to measure or estimate chest and abdominal volumes. RIP can also be used to measure the synchrony between the chest and the abdomen as the infant breathes, with asynchronous breathing implying increased respiratory effort and in some infants impending respiratory failure (Allen et al., 1990; Reiterer et al., 2015).

Traditionally, resistance of the total respiratory system was calculated from measurements of distending pressure, volume, and flow (see Fig. 44.3). For this calculation, points of equal volume are chosen during inspiration and expiration. The gas flow and the distending pressure are measured at each point. The pressure needed to overcome elastic forces should be the same for inspiration and expiration, and therefore the pressures should cancel out. Total resistance, consequently, is equal to distending pressure at the inspiratory point minus distending pressure at the expiratory point divided by the sum of the respective inspiratory and expiratory point gas flows. Subsequently, investigators simplified these calculations by measuring distending pressure, gas flow, and volume (see Fig. 44.3), then fitting these measurements to the equation of motion (Eq. 3) using multiple linear regression techniques and solving for the coefficients $1/C$ and R (Bhutani et al., 1988). Calculations of pulmonary function by modern ventilators use much the same process.

Calculation of lung compliance, however, requires measurements of distending pressure and volume (see Figs. 44.1 and 44.3) obtained when the lung is at rest. The choice of distending pressure determines the site of the pressure measurement, and gas volume is obtained by integration of the measurements of flow. As mentioned previously, the mechanical behavior of the respiratory system (chest wall and

lung) can be decoupled effectively by measurement of pleural pressure. Because it is not feasible to measure pleural pressure, esophageal pressure measured in the distal third of the esophagus, with use of an air-filled catheter attached to a pressure transducer, can be used to estimate pleural pressure. Thus transpulmonary pressure is estimated as the difference between airway pressure and esophageal pressure and is useful in measuring lung and chest wall mechanics.

Static compliance is the compliance measured when the infant is completely passive and can be estimated with use of an inspiratory hold at the end of inhalation during assisted ventilation (McCann et al., 1987) by instillation of a known volume of gas into the lung, followed by measurement of airway pressure at equilibrium in the absence of airflow and respiratory muscle activity (see Figs. 44.1 and 44.3) or by the use of a weighted spirometer (Tepper et al., 1984).

Calculations of compliance are affected by lung size. For example, if a 5-cmH₂O distending pressure results in a 25-mL increase in lung volume in a newborn, the calculated lung compliance is 5 mL/cmH₂O. In an adult, the same 5-cmH₂O distending pressure increases the lung volume by roughly 500 mL, and the calculated compliance is 100 mL/cmH₂O. Although the calculated lung compliances are different, the forces needed to perform tidal ventilation are similar (i.e., lung function is normal in both circumstances). This example points out that if lung compliances are to be compared, they must be corrected for size. One usually does this by dividing compliance by resting lung volume to get *specific compliance*. For the newborn, resting lung volume is roughly 100 mL, so specific compliance is 0.05 mL/cmH₂O per milliliter lung volume. For the adult, resting lung volume is nearly 2000 mL, so specific compliance is 0.05 mL/cmH₂O per milliliter lung volume—identical to that of the newborn.

Lung compliance changes with volume history, meaning that it decreases with fixed tidal volumes and increases after deep breaths that recruit air spaces that may have been poorly ventilated or collapsed. The periodic sigh in spontaneous breathing is typically associated with an increase in lung compliance and in oxygenation (Frappell and MacFarlane, 2005).

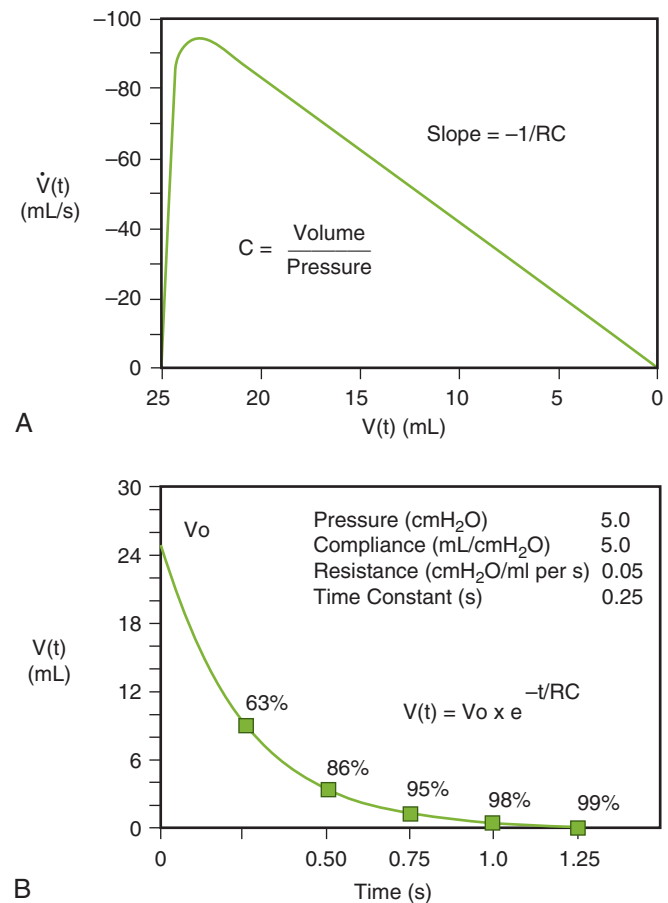

Because of the difficulties associated with trying to achieve a steady state to measure static compliance, many investigators calculate a “dynamic compliance” and take advantage of the fact that gas flow in and out of the lung is transiently equal to zero at the end of inspiration and the end of expiration (see Fig. 44.3). Measuring lung volume and distending pressures at these two points of rest allows calculation of compliance by division of the change in volume by the concomitant change in distending pressure.

In the normal infant it is generally assumed that *dynamic* compliance is equal to *static* compliance. However, many respiratory disorders result in nonhomogeneous increases in small airway resistance in the lung (Table 44.1). As a result, in infants who are tachypneic or who have elevated airway resistance, the *dynamic* compliance may underestimate the *static* compliance of the lung (Katier et al., 2006).

Discussion of a partial solution to the equation of motion for the respiratory system can shed some light on this discrepancy. The behavior of the respiratory system during passive exhalation is a special situation for which a solution can be obtained relatively easily with use of the occlusion technique (McIlroy et al., 1963; Lesouef et al., 1984; Katier et al., 2005). Before a passive exhalation maneuver, the infant is given a positive pressure breath, and the airway is occluded—invoking the Hering–Breuer reflex and a brief

apnea. Airway pressure is measured, and the occlusion is released. Expired gas flow is measured with a pneumotachometer and integrated to volume; flow is then plotted as a function of volume (Fig. 44.5A). During a passive exhalation, no external forces are acting on the respiratory system (airway pressure or $P(t) = 0$), so the equation of motion simplifies to a first-order differential equation:

$$(V[t] \times 1/C) + (\dot{V}[t] \times R) = 0.$$

• **Fig. 44.5** (A) Flow of gas out of the lung versus volume of gas remaining in the lung, $V(t)$, for a passive exhalation. Flow of gas out of the lung is negative by convention. After an initial sharp increase, flow decreases linearly as the lung empties. Static compliance of the respiratory system is obtained by division of the exhaled volume by the airway pressure at the beginning of the passive exhalation. Resistance is calculated from the slope of the flow–volume plot ($-1/RC$) and the compliance. This technique has the advantage of not requiring measurements of pleural pressure and being relatively unaffected by chest wall distortion. (B) $V(t)$ as a function of time for a passive exhalation. The graph is an exponential with the equation

$$V(t) = V_0 \times e^{-t/RC},$$

where V_0 is the starting volume, and e is the base of the natural logarithm (roughly 2.72). For this example the time constant of the respiratory system (Trs) is roughly 0.25 second. Calculations show that when exhalation persists for a time equal to the time constant ($t = 0.25$ second = $1 \times Trs$), 63% of the gas in the lung is exhaled. For $t = 2Trs$, 86% of the gas is exhaled; for $t = 3Trs$, 95% of the gas is exhaled; for $t = 4Trs$, 98% of the gas is exhaled; and for $t = 5Trs$, 99% of the gas is exhaled. If expiration is interrupted before $t = 3Trs$, gas is trapped in the lung.

Rearrangement yields the linear equation

$$(5) \quad \dot{V}(t) = -\left(\frac{1}{RC}\right) \times (V[t]),$$

where the slope is $-1/RC$, which can be determined by a linear regression of $\dot{V}(t)$ versus $V(t)$. This equation states that during passive exhalation, flow plotted against volume is a straight line with slope $-1/RC$. Since we can calculate volume from the flow-volume curve, we can use the pressure measured during the inspiratory hold to calculate compliance and the slope of the line to calculate resistance. The quantity RC has the units of time, is termed the *respiratory system time constant* (Trs), and defines the rate at which the lung deflates during a passive exhalation (see Fig. 44.5B). Time constants affect the rate of lung inflation in much the same manner.

Several investigators have noted that with obstructive lung disease the expiratory flow-volume plot may not be linear but curved (concave), and the fit to a straight line is poor (Jarriel et al., 1993; Numa et al., 2001). These studies found that the plots fit a biexponential function much better—with one exponential describing the behavior of well-ventilated lung units and the other describing the behavior of poorly ventilated lung units. The studies were designed to measure the effects of bronchodilators on airway resistance in infants with obstructive lung disease. The effect of bronchodilators on airway resistance in well-ventilated lung units was small (Numa et al., 2001) in one study and absent in the other (Jarriel et al., 1993). Both studies found that administration of bronchodilators resulted in a substantial reduction in airway resistance in poorly ventilated lung units. In both studies the time constants of well-ventilated lung units were relatively normal and much smaller than those of the poorly ventilated lung units (2.5 to 7 times smaller). These data imply that the well-ventilated lung units would have almost completely emptied before the poorly ventilated units reached even one time constant. Any measurements of mechanics that depend on the initial rate of gas flow only (from direct measurements of flow or from estimates obtained by RIP would miss most of the flow from poorly ventilated lung units, underestimate resistance for the lung as a whole, and miss the important effect of the bronchodilators and other interventions on the poorly ventilated parts of the lung.

This compartmentalization of lung units also impacts lung inflation. If lung compliance remains relatively uniform, the product of resistance and compliance (Trs) will vary throughout the lung. During lung inflation, units with normal resistance have the lowest Trs and fill rapidly; units with high resistance have a greater Trs and fill more slowly. At rapid respiratory rates when the duration of inspiration is short, only those lung units with a small Trs are ventilated. In effect, the ventilated lung becomes smaller. As discussed earlier, as the lung becomes smaller, its measured compliance decreases. Therefore in infants with ventilation inhomogeneities, dynamic lung compliance decreases as respiratory rate increases. This decrease in lung compliance with increasing respiratory rate is termed the *frequency dependence of compliance*, and it is suggestive of inhomogeneous small airway obstruction.

FRC is measured by inert gas dilution techniques (helium dilution) or inert gas displacement (nitrogen washout) (Fig. 44.6). Both of these techniques measure gas that communicates with the airways. The total volume of gas in the thorax at the end of expiration (thoracic gas volume) can be measured with a body plethysmograph and application of Boyle's law. This technique measures

• **Fig. 44.6** (A) Measurement of functional residual capacity (FRC) by helium dilution. At the end of exhalation, the infant breathes from a bag containing a known volume (V_{bag}) and concentration of helium (He_1) in oxygen. The gas in the infant's lungs dilutes the helium oxygen mixture to a new concentration (He_2): $FRC = bag\ volume \times (He_1 - He_2)/He_1$. (B) Measurement of thoracic gas volume (TGV) using a plethysmograph. The infant breathes spontaneously in a sealed body plethysmograph (Pbox). At the end of exhalation, the airway is closed with a shutter. As the infant attempts to inspire against the shutter, the volume of the thorax increases, and airway pressure decreases. The increase in volume of the thorax can be measured from the change in the pressure inside of the Pbox. By Boyle's law, $P \times TGV = (P - \Delta P) \times (TGV + \Delta V)$, where P is atmospheric pressure, $(P - \Delta P)$ is airway pressure during occlusion, and $(TGV + \Delta V)$ is thoracic volume during occlusion. Therefore $TGV = (P - \Delta P) \times \Delta V / \Delta P$. Because ΔP is small compared with P , this can be simplified to $TGV = P \times \Delta V / \Delta P$.

all gas in the thorax—even trapped gas that is not in contact with the airways. Obviously, FRC measured by inert gas dilution is less than thoracic gas volume if significant volumes of trapped gas are present.

Alveolar Ventilation

The tissues of the body continuously consume oxygen (O_2) and produce carbon dioxide (CO_2) (Fig. 44.7). The primary function of the circulation is to pick up O_2 from the lungs and deliver it to the tissues and to pick up CO_2 from the tissues and deliver it to the lungs. The exchange of O_2 and CO_2 with the blood occurs within the alveolar volume of the lungs. The alveolar volume acts as a “large sink” from which O_2 is continuously extracted by the blood and to which CO_2 is continuously added. This mechanism for acquiring O_2 from the atmosphere and excreting CO_2 into the atmosphere is the alveolar ventilation (Slonim and Hamilton, 1987).

The alveolar volume of the lung includes all lung units capable of exchanging gas with mixed venous blood: respiratory bronchioles, alveolar ducts, and alveoli. Because the conducting airways do not participate in gas exchange, they constitute the anatomic dead space (V_{DS}). At the end of exhalation, the FRC is the sum of the volume of gas in the alveolar volume and in the anatomic V_{DS} . During normal breathing the amount of gas entering and leaving the lung with each breath is the tidal volume (V_T):

$$Minute\ Ventilation\ (\dot{V}) = V_T \times Respiratory\ Rate\ (RR).$$

• **Fig. 44.7** Coupling of alveolar ventilation with tissue oxygen consumption. *Lt.*, Left side of the heart; *Rt.*, right side of the heart.

Part of each V_T is wasted ventilation because it moves gas in and out of the V_{DS} . Therefore alveolar ventilation (\dot{V}_A) can be expressed as

$$(6) \quad \dot{V}_A = (V_T - V_{DS}) \times (RR).$$

Alveolar ventilation is an intermittent process, whereas gas exchange between the alveolar space and the blood occurs continuously. Because arterial O₂ and CO₂ tensions (PaO₂ and PaCO₂) are roughly equal to the O₂ and CO₂ tensions within the alveolar space, these fluctuations in breathing could result in intermittent hypoxemia and hypercarbia. Fortunately the lung has a large buffer—the FRC. The FRC is four to five times as large as the V_T ; therefore only a fraction of the total gas in the lung is exchanged during normal breathing. This large buffer continues to supply O₂ to the blood during expiration and acts as a sump to accept CO₂ from the blood, so alveolar O₂ and CO₂ tensions (PAO₂ and PACO₂) change little throughout the ventilatory cycle.

Alveolar ventilation is linked tightly to metabolism. When alveolar ventilation is uncoupled from the body's metabolic rate, hypoventilation or hyperventilation results. During hypoventilation, less O₂ is added to the alveolar space than is removed by the blood, and less CO₂ is removed from the alveolar space than is added by the blood. As a result, PAO₂ decreases and PACO₂ increases. The net result of hypoventilation is hypoxemia and hypercapnia.

Administration of supplemental O₂ increases the quantity of O₂ in each breath delivered to the alveolar space, and it may prevent arterial hypoxemia. For example, suppose a 1-kg male infant has a V_T of 6 mL, an anatomic V_{DS} of 2 mL, and a respiratory rate of 40 breaths per minute. His alveolar ventilation is 160 mL per minute $[(6 \text{ mL} - 2 \text{ mL}) \times 40/\text{minute}]$. If he breathes room air (21% O₂), he delivers 33.6 mL of O₂ to the alveolar space every minute $(160 \text{ mL/minute} \times 0.21)$. If he maintains the same V_T but breathes only 20 times per minute, his alveolar ventilation decreases to 80 mL per minute, only 16.8 mL of O₂ $(80 \text{ mL/minute} \times 0.21)$ is delivered to the alveolar space each minute, and his PAO₂ and PaO₂ decrease. If he is allowed to breathe 50% O₂, O₂ delivery to the alveolar space increases to 40 mL per minute $(80 \text{ mL/minute} \times 0.50)$, and his PAO₂ and PaO₂ both increase. Because O₂ administration has no effect on the accumulation of CO₂, it does not prevent hypercapnia.

Hyperventilation delivers more O₂ to the alveolar space than can be removed by the blood and removes more CO₂ than can be added by the blood. As a result, PAO₂ increases and PACO₂ decreases.

Measurements of alveolar ventilation and anatomic V_{DS} in the infant rely on the relationship between CO₂ production \dot{V}_{CO_2} , \dot{V}_A , and P_ACO₂. The mathematical expression of this relationship states (Cook et al., 1955)

$$(7) \quad F_A \text{CO}_2 = \dot{V}_{CO_2} / \dot{V}_A.$$

$F_A \text{CO}_2$ is the fraction of CO₂ in total alveolar gas, or

$$(8) \quad F_A \text{CO}_2 = P_A \text{CO}_2 / (P_B - 47).$$

P_B is the barometric pressure, and 47 mmHg is the vapor pressure of water at body temperature.

Therefore

$$(9) \quad \dot{V}_A = [\dot{V}_{CO_2} \times (P_B - 47)] / P_A \text{CO}_2.$$

If minute ventilation (\dot{V}) is measured, dead space ventilation (\dot{V}_D) is calculated as

$$(10) \quad \dot{V}_D = \dot{V} - \dot{V}_A,$$

and V_{DS} is calculated by multiplication by the respiratory rate.

This method measures the anatomic V_{DS} in the lung. As seen in the next section, portions of some gas-exchanging units in the lung can also function as V_{DS} ; therefore the total V_{DS} , or the physiologic V_{DS} , may be greater than the anatomic V_{DS} . Physiologic V_{DS} is calculated by substitution of PaCO₂ for PACO₂ in Eq. (9). When PaCO₂ = PACO₂, all the dead space is anatomic dead space, and the gas-exchanging units are all functioning normally. As physiologic V_{DS} increases, however, PaCO₂ increases relative to PACO₂. Therefore the difference between PaCO₂ and PACO₂ (aA.DCO₂) is a measure of the efficiency of gas exchange in the lung.

For clinical purposes, \dot{V}_{CO_2} in Eq. (9) is assumed to be a constant so that \dot{V}_A is proportional to $1/\text{PACO}_2$. Thus increased PACO₂ means that alveolar ventilation has decreased; decreased PACO₂ means that alveolar ventilation has increased.

TABLE 44.2**Indices of Ventilation–Perfusion Imbalance in the Normal Newborn Breathing Room Air**

| | Aa.D _O ₂ (mmHg) | $\dot{Q}_t - \dot{Q}_{va}$ | aA.DN ₂ (mmHg) | $\dot{Q}_t - \dot{Q}_o$ | $\dot{Q}_t - \dot{Q}_s$ | aA.DCO ₂ (mmHg) |

Ventilation–Perfusion Relationships

Ideally, ventilation and perfusion of the lung are evenly matched, $\dot{V}/\dot{Q} = 1$, both in the lung as a whole and in each individual air space. The air spaces receive O₂ from the inspired gas and CO₂ from the blood. O₂ is transported into the blood, while CO₂ is transported to the atmosphere. Even though $\dot{V}/\dot{Q} = 1$, CO₂ and O₂ are exchanged in the lung at the same ratio at which they are exchanged in the tissues: a little less CO₂ is transported out than O₂ is transported in, and the respiratory exchange ratio *R* equals 0.8. If there is no diffusion defect, the gas composition of the air spaces and the blood comes into equilibrium. Nitrogen (N₂) makes up the balance of dry gas. The sum of partial pressures of all gases in the air spaces must equal atmospheric pressure or they will collapse. The ideal alveolar gas composition is PAO₂ = 100 mmHg, PACO₂ = 40 mmHg, PAN₂ = 573 mmHg, and PAH₂O = 47 mmHg at an atmospheric pressure of 760 mmHg. The ideal arterial blood composition is the same. Therefore differences between alveolar and arterial gas composition under ideal circumstances are all zero. In the following equations, inspired gas is denoted “I” (inspired oxygen tension is written as P_{IO}₂, the fraction of oxygen in inspired gas is F_{IO}₂, the inspired nitrogen tension is P_{IN}₂, and the fraction of nitrogen in inspired gas is F_{IN}₂. The values for PACO₂, the inspired oxygen tension (P_{IO}₂), and the fraction of oxygen in inspired gas (F_{IO}₂) can be used to calculate the ideal alveolar gas composition with use of the alveolar gas equation (Farhi, 1966):

(11)

$$PAO_2 = P_{IO_2} - PACO_2 \times [F_{IO_2} + (1 - F_{IO_2})/R],$$

where

(12)

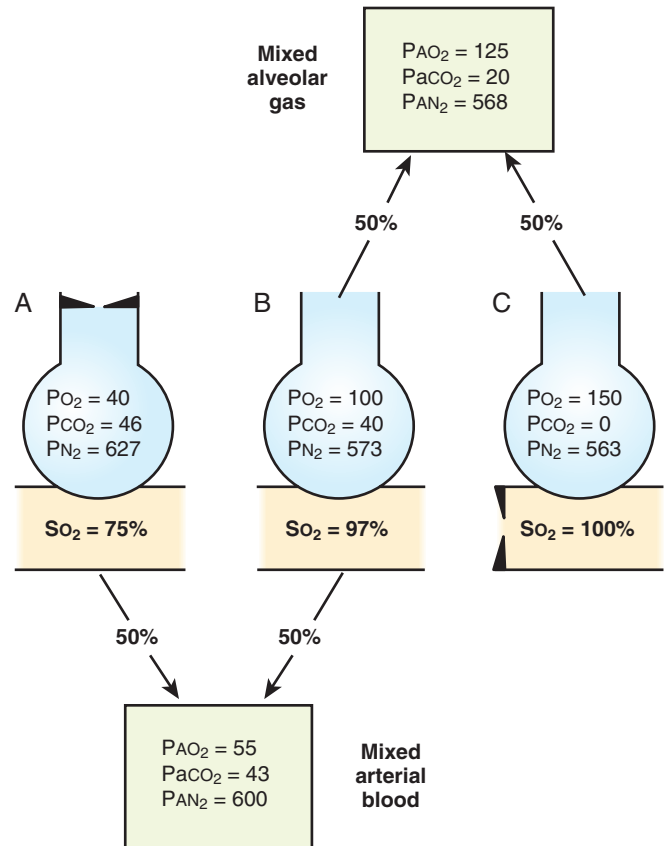

$$P_{IO_2} = F_{IO_2} \times (P_B - PH_2O)$$

and

(13)

$$PAN_2 = F_{IN_2} \times [PACO_2 \times (1 - R)/R + (P_B - PH_2O)].$$

Under normal circumstances, and certainly in the presence of lung disease, this ideal situation is not the case; some air spaces receive more ventilation than perfusion, and others receive more perfusion than ventilation (Table 44.2). A reduction of ventilation may occur because of atelectasis, alveolar fluid, or airway narrowing. Reduced ventilation in one part of the lung may cause increased ventilation elsewhere. A reduction of perfusion may occur if air spaces are collapsed or overdistended or because of gravitational effects, and increased perfusion may occur in congenital heart disease. As with ventilation, reduced perfusion in one part of the lung may cause

• **Fig. 44.8** Three-compartment model of the lung with $\dot{V}/\dot{Q} = 0$ (A), $\dot{V}/\dot{Q} = 1$ (B), and $\dot{V}/\dot{Q} = \text{infinity}$ (C). The inspired gas is room air, and (B) is the ideal compartment. The sum of alveolar gas partial pressures is always 713 mmHg. So₂ is oxygen saturation in capillary blood. PaO₂ is read from the oxygen dissociation curve for a saturation of 86%. By calculated differences, Aa.DO₂ is 70 mmHg, aA.DCO₂ is 23 mmHg, and aA.DN₂ is 32 mmHg.

increased perfusion in other regions. If an air space is relatively overventilated (high \dot{V}/\dot{Q}), its gas composition trends toward that of inspired gas, which in the case of room air is PO₂ = 150 mmHg and PCO₂ = 0 mmHg. If an air space is relatively underventilated (low \dot{V}/\dot{Q}), its gas composition trends toward that of mixed venous blood, which is PvO₂ = 40 mmHg and PVCO₂ = 46 mmHg. What counts is the $\dot{V}/\dot{Q} = 1$ ratio, not absolute values of \dot{V} or \dot{Q} (West, 1986).

To understand \dot{V}/\dot{Q} imbalance, it is common to view the lung as a three-compartment model (Fig. 44.8): $\dot{V}/\dot{Q} = 0$ (see Fig. 44.8A); $\dot{V}/\dot{Q} = 1$ (see Fig. 44.8B); and $\dot{V}/\dot{Q} = \text{infinity}$ (see Fig. 44.8C). The O₂ saturation of blood in each compartment depends on PO₂

and the O_2 dissociation curve. For illustrative purposes, in a badly diseased lung, 50% of ventilation goes to $\dot{V}/\dot{Q} = 1$, and 50% goes to $\dot{V}/\dot{Q} = \text{infinity}$, whereas 50% of perfusion goes to $\dot{V}/\dot{Q} = 1$, and 50% goes to $\dot{V}/\dot{Q} = 0$. Perfusion of $\dot{V}/\dot{Q} = 0$ causes venous admixture, whereas ventilation of $\dot{V}/\dot{Q} = \text{infinity}$ causes alveolar V_{DS} . The mixed alveolar gas composition is easily calculated as the mean. For mixed arterial blood, PO_2 must be read from the O_2 dissociation curve, but because the CO_2 dissociation curve is fairly linear, the values for CO_2 are easily calculated as the mean. The abnormalities in the distribution of \dot{V} and \dot{Q} have created $Aa.DO_2 = 70$ mmHg, $aA.DCO_2 = 23$ mmHg, and $aA.DN_2 = 32$ mmHg (see Fig. 44.8; Markello et al., 1972; Corbet et al., 1974). $Aa.DO_2$ is greater than the sum of $aA.DCO_2$ and $aA.DN_2$ because the O_2 dissociation curve is not linear. Of course, the situation in most lungs is not as extreme as the one illustrated. From this illustration, however, it can be seen that:

1. Open low \dot{V}/\dot{Q} units produce increased $Aa.DO_2$, significant hypoxemia, and increased $aA.DN_2$, but because they are poorly ventilated and have $PACO_2$ close to the ideal value, they do not change $aA.DCO_2$ significantly.
2. High \dot{V}/\dot{Q} units produce increased $Aa.DO_2$ without hypoxemia and increased $aA.DCO_2$, but because they are poorly perfused and have PAN_2 close to the ideal value, they do not change $aA.DN_2$ significantly.

For the calculation of $Aa.DO_2$ and $aA.DN_2$, it is customary to calculate the ideal alveolar gas composition for O_2 and N_2 from the alveolar gas equations and use these values with those measured for arterial PO_2 and PN_2 . This emphasizes that part of the $Aa.DO_2$ and $aA.DN_2$ is responsible for hypoxemia. For $aA.DCO_2$, both an arterial and mixed alveolar sample are required.

In the newborn a third compartment in the model is important. A significant part of the venous return may be shunted from right to left at the foramen ovale, ductus arteriosus, pulmonary arteriovenous vessels, or lung mesenchyme without airway development, thus adding mixed venous to mixed arterial blood. This substantially increases $Aa.DO_2$ but has little effect on $aA.DCO_2$ and no effect on $aA.DN_2$. The last of these is because there is no significant exchange of N_2 in the body, so venous and arterial PN_2 are the same. The effect on $aA.DCO_2$ is small because venous PCO_2 is only slightly higher than arterial PCO_2 . From this analysis it can be seen that hypoxemia is produced by a true right-to-left shunt and open low \dot{V}/\dot{Q} units. Diffusional problems are not thought to be important in the newborn. Hypoxemia may be modeled as a venous admixture, the part of mixed venous blood, expressed as a fraction of cardiac output, that when added to blood equilibrated with an ideal lung would produce the measured arterial oxygen saturation. It is calculated as follows:

$$(14) \quad \frac{\dot{Q}_{va}}{\dot{Q}_t} = \frac{C_cO_2 - C_aO_2}{C_cO_2 - C_vO_2},$$

where \dot{Q}_{va}/\dot{Q}_t refers to a venous admixture, CO_2 refers to oxygen content, subscript c refers to a pulmonary capillary, subscript a refers to arterial blood, and subscript v refers to mixed venous blood. For practical application, C_vO_2 is calculated from a constant $av.O_2$ difference, which does introduce an error.

If an infant breathes 100% O_2 for 15 minutes, most N_2 is washed out of the lung, and PO_2 in open low \dot{V}/\dot{Q} units becomes so high that associated blood is 100% saturated with O_2 . The remaining venous admixture is attributed to true right-to-left shunt (\dot{Q}_s/\dot{Q}_t). If the total venous admixture \dot{Q}_{va}/\dot{Q}_t is measured while

the infant is breathing room air, then true shunt (\dot{Q}_s/\dot{Q}_t) measured while breathing 100% O_2 , the venous admixture caused by open low \dot{V}/\dot{Q} units (\dot{Q}_o/\dot{Q}_t) can be calculated as the difference.

Heart–Lung Interaction

Effects of the Lung on the Heart

There exists considerable potential for the lung to affect the heart. Because they share the thoracic cavity, changes in intrathoracic pressure accompanying lung inflation are transmitted directly to the heart. In addition, all of the blood leaving the right ventricle must traverse the pulmonary vascular bed, so changes in pulmonary vascular resistance may greatly affect right ventricular function.

Effects of Changes in Intrathoracic Pressure on the Heart

Negative Intrathoracic Pressure

During spontaneous inspiratory efforts, the chest wall and diaphragm move outward, intrathoracic volume increases, and intrathoracic pressure decreases (Fig. 44.9A). The heart also resides within the thoracic cavity and is subject to the same negative intrathoracic pressure during inspiration. With a decrease in intrathoracic pressure, the heart increases in volume, and the pressure within its chambers decreases relative to atmospheric pressure. Analogously to the lung, when the pressure within the heart decreases, blood is literally sucked back into the heart from systemic veins and arteries. On the right side of the heart, the phenomenon serves to increase the flow of blood from systemic veins into the right atrium, increasing right ventricular preload and ventricular output. On the left side of the heart, ventricular ejection is impaired. During systole the left ventricle must overcome not only the load imposed by the systemic vascular resistance but also the additional load imposed by the negative intrathoracic pressure (McGregor, 1979).

In infants with normal lungs, spontaneous respiratory efforts result in relatively small swings in pleural pressure (2 to 3 mmHg) that have little effect on the pressure within the heart. With airway

• **Fig. 44.9** (A) Negative intrathoracic pressure increases the volume of the heart and decreases the pressure within the chambers. This facilitates return of blood from the superior vena cava (SVC) and inferior vena cava (IVC) to the right atrium (RA) and impedes ejection of blood from the left ventricle (LV) into the extrathoracic aorta. (B) Positive intrathoracic pressure decreases the volume of the heart and increases pressure within its chambers. This impedes blood return to the RA and augments ejection of blood from the LV.

obstruction or parenchymal lung disease, however, swings in pleural pressure can be much greater (5 to 20 mmHg), and systemic arterial pressure may fluctuate by as much as 5 to 20 mmHg depending on where in the respiratory cycle ventricular systole occurs. In older children with asthma or some other form of airway obstruction, these fluctuations in blood pressure constitute *pulsus paradoxus* and are indicative of severe airway obstruction.

Positive Intrathoracic Pressure

During positive pressure ventilation, the lung inflates and pushes the chest wall and diaphragm outward (see Fig. 44.9B). This outward push generates a pressure in the thoracic space that is greater than atmospheric pressure. The magnitude of the increase (relative transmission of airway pressure to the pleural space) is determined by the volume of lung inflation (which, in turn, is determined by the airway pressure and lung compliance) and by the compliance of the chest wall and diaphragm. If the lung is compliant and the chest wall rigid, little airway pressure is lost inflating the lung, but considerable pressure is generated in the thoracic cavity as the lung attempts to push the rigid chest wall outward. In this instance, intrathoracic pressure (intrapleural pressure) is much greater than atmospheric pressure and is nearly equal to airway pressure. If the lung is poorly compliant and the chest wall is highly compliant, most of the airway pressure is dissipated in an attempt to inflate the lungs, and little is transmitted to the thoracic cavity.

The effects of positive intrathoracic pressure on the heart are opposite those of negative intrathoracic pressure. The heart is compressed by the lungs and chest wall, and blood is squeezed out of the heart and the thoracic cavity. Return of blood from systemic veins is impaired, and right ventricular preload and output decrease. If the increase in intrathoracic pressure coincides with ventricular systole, the effect is to augment left ventricular ejection and reduce the load on the left ventricle.

In the infant undergoing positive pressure ventilation, the degree to which lung inflation compromises venous return is related to the relative compliances of the lung and chest wall. If the infant's lung is poorly compliant and the chest wall is compliant, as in hyaline membrane disease, there is little effect of lung inflation on venous return. If the infant's lung is normally compliant but tight abdominal distention prevents descent of the diaphragm, intrathoracic pressure increases dramatically during positive pressure

ventilation, and venous return and cardiac output can be impaired. This mechanism may help explain the circulatory instability of infants after gastroschisis repair. A similar situation may arise in the preterm infant with pulmonary interstitial emphysema and massive lung overinflation. In such an infant, the heart is tightly compressed between the hyperinflated lungs and the other structures of the mediastinum and the diaphragm. Venous return may be severely limited and venous pressures so increased that massive peripheral edema often accompanies the reduction in cardiac output.

Although the effects of increased pleural pressure on the right atrium are detrimental, the effects on the left ventricle may be extremely beneficial (Niemann et al., 1980). During cardiopulmonary resuscitation the chest wall is compressed against the lung, and intrathoracic pressure increases. Because the left ventricle is in the thorax, left ventricular pressure increases as well. A gradient is created, favoring flow of blood out of the ventricle and thorax and into the extrathoracic systemic circulation. Between chest compressions, elastic recoil causes the chest wall to pull away from the lung and heart, decreasing pleural pressure, favoring return of venous blood, and priming the heart for the next chest compression. A similar phenomenon may result in augmentation of systemic pressure when ventilator breaths coincide with ventricular systole.

Effect of Lung Inflation on Pulmonary Vascular Resistance

The pulmonary interstitium comprises three different interconnected connective tissue compartments, each containing a different element of the pulmonary circulation (Fishman, 1986). The first—the perivascular cuffs—consists of a sheath of fibers that contain the preacinar pulmonary arteries, lymphatics, and bronchi. The second consists of the intersegmental and interlobular septa and contains pulmonary veins and additional lymphatics. The third connects these two within the alveolar septa and contains most of the pulmonary capillaries. The first and second compartments represent the extra-alveolar interstitium, whereas the third represents the alveolar interstitium. The perivascular cuffs are surrounded by alveoli and expand during lung inflation (Fig. 44.10A). As a result, pressure within each cuff decreases, distending extra-alveolar blood vessels and decreasing their resistance to blood flow. The alveolar interstitium lies between adjacent alveoli and contains most of the gas-exchanging vessels in the lung. These vessels are exposed to

• **Fig. 44.10** (A) Effects of lung inflation on extra-alveolar vessels. (B) Effects of lung inflation on alveolar vessels. (C) Effect of lung volume on pulmonary vascular resistance (PVR; solid line). Inflation is from residual volume (RV) to functional residual capacity (FRC) to total lung capacity (TLC). The dashed line represents alveolar vessels; the dotted line represents extra-alveolar vessels.

alveolar pressure on both sides and during lung inflation (see Fig. 44.10B) are compressed so that their resistance to blood flow increases.

Therefore during lung inflation (see Fig. 44.10C), the resistance in extra-alveolar vessels decreases, whereas resistance in alveolar vessels increases. As a result, the overall pulmonary vascular resistance decreases initially, with lung inflation reaching its nadir at FRC, and then increases with further inflation.

If transition from intrauterine to extrauterine life is to be successful, after birth all of the right ventricular output must traverse the pulmonary vascular bed. To some extent this adaptation is facilitated by a reduction in pulmonary vascular resistance that occurs with inflation of the lungs (see Fig. 44.10C) to a stable FRC. Inflation of the lung beyond FRC increases pulmonary vascular resistance. If care is not taken during positive pressure

ventilation, it is possible to inflate the lung to the point that alveolar vessels close and blood flow through the lung is impaired. When this occurs, either cardiac output decreases or the blood bypasses the lung via the foramen ovale or ductus arteriosus. Clinically, this is manifest as circulatory insufficiency from impaired right ventricular output or hypoxemia from right-to-left shunting of blood or both.

Effects of the Heart on the Lung

Pulmonary Edema

Pulmonary edema is the abnormal accumulation of water and solute in the interstitial and alveolar spaces of the lung (Staub, 1974; Bland et al., 1985). In the lung, fluid is filtered from capillaries in the alveolar septa into the alveolar interstitium (Fig. 44.11A)

• **Fig. 44.11** (A) In the lung, fluid is continuously filtered out of vessels in the microcirculation into the interstitium and then returned to the intravascular compartment by the lymphatics. Only when the rate of filtration exceeds the rate of lymphatic removal can fluid accumulate in the interstitium. Spillover of fluid into the alveolar space occurs only when the interstitial space fills or when the alveolar membrane is damaged. It has recently been shown that the alveolar epithelium is capable of pumping fluid from the alveolar space back into the interstitium as protection against alveolar flooding or to aid in the resolution of alveolar edema. (B) Fluid flows out of vessels at a flow rate (\dot{Q}_f) that is equal to the driving pressure for fluid flow (ΔP) times the filtration coefficient (K_f): $\dot{Q}_f = K_f \times \Delta P$. K_f can be thought of as the relative permeability of the vascular bed to fluid flux. K_f in the normal lung is a small number, so despite a driving pressure of roughly 5 mmHg, the net rate of fluid filtration is approximately 1 to 2 mL/kg per hour. (C) The driving pressure for fluid flow out of the microvascular bed represents a balance of two sets of pressures. Within the blood vessel, hydrostatic pressure tends to push fluid out of the vessel into the interstitium. This pressure is partially opposed by a smaller hydrostatic pressure within the interstitium pushing fluid back into the blood vessel. Within the blood vessel, there also exists a discrete oncotic pressure that results predominantly from intravascular albumin that tends to draw fluid from the interstitium back into the blood vessel. This pressure is partially opposed by an interstitial oncotic pressure tending to draw fluid from the blood vessel into the interstitium. (D) The intravascular hydrostatic pressure must be less than pulmonary artery pressure (P_{pa}) for blood to flow into the microvascular bed and greater than left atrial pressure (P_{la}) for blood to flow out. Intravascular pressure within the microvascular bed is given roughly by $P_{mv} = [0.4 \times (P_{pa} - P_{la}) + P_{la}]$. The interstitial hydrostatic pressure is roughly equal to alveolar pressure. The intravascular oncotic pressure can be calculated from the plasma albumin concentration. The interstitial oncotic pressure is roughly two-thirds of the intravascular oncotic pressure. The balance of these pressures favors filtration out of the vessel (in the normal lamb, this pressure is roughly 5 mmHg).

• BOX 44.1 Increased Intravascular Hydrostatic Pressure

Increased Left Atrial Pressure

and then siphoned into the lower-pressure extra-alveolar interstitium. The extra-alveolar interstitium contains the pulmonary lymphatics, and under normal conditions, they remove fluid from the lung so that there is no net accumulation in the interstitium. Pulmonary edema results only when the rate of fluid filtration exceeds the rate of lymphatic removal. There are only three mechanisms by which this can occur (see Fig. 44.11B): (1) the driving pressure for fluid filtration (filtration pressure) increases, (2) the permeability of the vascular bed (hence the filtration coefficient K_f) increases, or (3) lymphatic drainage decreases.

Increased Driving Pressure

Filtration pressure can be increased by increased intravascular hydrostatic pressure, decreased interstitial hydrostatic pressure, decreased intravascular oncotic pressure, or increased interstitial oncotic pressure (see Fig. 44.11C–D). By far the most common cause of increased filtration pressure is increased intravascular hydrostatic pressure (Box 44.1). In the newborn, intravascular hydrostatic pressure increases with increased left atrial pressure from volume overload or a number of congenital and acquired heart defects. In the preterm and term newborn, evidence suggests that alterations in pulmonary blood flow that are independent of any change in left atrial pressure may also influence fluid filtration in the lung. Preterm infants with patent ductus arteriosus and left-to-right shunts exhibit signs of respiratory insufficiency before they develop any evidence of heart failure, and experiments performed in newborn lambs show that fluid filtration in the lung can be increased by increase of pulmonary blood flow without increase of left atrial pressure (Feltz and Hansen, 1986). In the newborn with a reduced pulmonary vascular bed, either from lung injury or from hypoplasia, cardiac output appropriate for body size may represent a relative overperfusion to the lung and can result in increased fluid filtration. This phenomenon has been invoked to explain the lung edema that often complicates the course of the infant with bronchopulmonary dysplasia.

The exact cause of pulmonary edema that accompanies severe hypoxia or asphyxia in the newborn is still a controversial issue. Data suggest that it is the result of increased filtration pressure and not the result of any alteration in permeability. Heart failure accounts for some of the increased filtration pressure following

severe asphyxia. In addition, there may be some element of pulmonary venous constriction. Finally, there is evidence that hypoxia and acidosis may redistribute pulmonary blood flow to a smaller portion of the lung and result in relative overperfusion and edema, similar to that seen with anatomic loss of vascular bed (Hansen et al., 1984).

Several investigators have suggested that upper airway obstruction may cause pulmonary edema by decreasing interstitial hydrostatic pressure relative to intravascular hydrostatic pressure. Other data suggest, however, that with airway obstruction, vascular pressures decrease with intrapleural pressure in such a way that filtration pressure remains unchanged (Hansen et al., 1985).

Hypoproteinemia in infants results in a decrease in intravascular oncotic pressure. Its effects on filtration pressure, however, are blunted by the simultaneous decrease in protein concentration in the interstitial space of the lung. As a result, edema is unlikely to occur unless hydrostatic pressure also increases (Hazinski et al., 1986).

Increased Permeability

Another possible mechanism for increased fluid filtration in the lung is a change in the permeability of the microvascular membrane to protein—high-permeability pulmonary edema. In this form of edema the sieving properties of the microvascular endothelium are altered such that K_f increases and patients may develop pulmonary edema despite relatively normal vascular pressures (Albertine, 1985). Furthermore, even small changes in vascular pressures can result in a dramatic worsening of pulmonary status. High-permeability pulmonary edema usually implies either direct or indirect injury to the capillary endothelium of the lung. Direct injuries result from local effects of an inhaled toxin such as oxygen, severe alveolar overdistention (Carlton et al., 1990), or a massive increase in pulmonary capillary pressure. The latter is proposed as the mechanism for hemorrhagic pulmonary edema following surfactant administration in the presence of a patent ductus arteriosus. However, the benefits of surfactant administration vastly outweigh the risk of pulmonary hemorrhage (Raju et al., 1993; Pappin et al., 1994). Indirect injuries imply that the initial insult occurs elsewhere in the body and that the lung injury occurs secondarily. Sepsis is a classic example of indirect lung injury where neutrophils activated by bacterial toxins attack endothelial cells in the lung and increase permeability to water and protein (Brigham et al., 1974). Massive trauma to the central nervous system can also injure the pulmonary capillary bed by inducing massive arterial and venous constriction (Malik, 1985). In general, indirect injuries usually involve bloodborne mediators, such as leukocytes, leukotrienes, histamine, or bradykinin. In some instances the injury to the capillary membrane may be so severe that red blood cells may leak into the alveolar space (*pulmonary hemorrhage*). It is important to note that Cole et al. (1973) found that the hemorrhagic fluid has a very low hematocrit suggestive of severe pulmonary edema rather than any disorders of the coagulation system and that treatment should be focused on lowering vascular pressures.

Decreased Lymphatic Drainage

In the normal lung the rate of lung lymph flow is equal to the net rate of fluid filtration, and as long as lymphatic function can keep up with the rate of fluid filtration, water does not accumulate in the lung. Although lymphatics can actively pump fluid against a pressure gradient, this ability is limited, and lung lymph flow varies inversely with the outflow pressure (pressure in the superior vena cava). Several groups of investigators have demonstrated that,

in the presence of an increased rate of transvascular fluid filtration, the rate of fluid accumulation in the lung is substantially greater if systemic venous pressure is increased (Drake et al., 1985). Data suggest that the ability of the lymphatics to pump against an outflow pressure is impaired in the fetus and newborn. In fetal lambs, lymph flow ceases at an outflow pressure of roughly 15 mmHg (Johnson et al., 1996). This explains why pulmonary edema often complicates the course of infants with bronchopulmonary dysplasia and cor pulmonale and explains the particular problem of edema with pleural effusions complicating the postoperative course of patients following cavopulmonary shunts. Subsequent investigations showed that the ability of the lymphatics to pump can be affected by other mediators, with pumping increased by α -adrenergics and certain leukotrienes and impaired by nitric oxide, β -adrenergics (von der Weid, 2001), and products of hemolysis (Elias et al., 1990).

Congenital pulmonary lymphangiectasis is a rare form of pulmonary lymphatic dysfunction that can be characterized into two groups: (1) cases associated with congenital heart disease and (2) cases not associated with congenital heart disease. The cardiac anomalies may include hypoplastic left-sided heart syndrome, total anomalous pulmonary venous drainage, and pulmonary stenosis, including Noonan syndrome (France and Brown, 1971). The group that does not include associated cardiac anomalies may be of early or late onset and has a wide spectrum of severity. In some individuals the lesion is asymptomatic, whereas in others it can lead to severe respiratory failure, usually in the first few hours after birth but sometimes during the first few weeks or months of life. Most infants with this condition die early in the neonatal period. Pulmonary lymphangiectasis has been reported twice as often in males and has been seen in families (Scott Emaukpor et al., 1981).

Alveolar Space

The same factors that affect fluid balance across the lung are also present within the alveolar space. The absence of protein in the alveolar space means that the oncotic pressure gradient dramatically favors fluid flow from the alveolus into the pulmonary interstitium.

In addition, fluid filtered into the alveolar interstitium ordinarily moves rapidly along pressure gradients into the extra-alveolar interstitium, where it is removed by the lymphatics. The extra-alveolar interstitium has a large storage capacity, and fluid does not begin to spill over into the alveoli and airways until total lung water is increased by more than 50%. Even then, because K_f for the alveolus is very low, alveolar flooding probably implies damage to the alveolar membrane. This damage may result from many of the same factors affecting vascular permeability, such as oxygen toxicity, sepsis, or alveolar overdistension. There is a growing body of evidence that the alveolar epithelium is capable of pumping fluid from the alveolar space back into the interstitium, and this represents another defense mechanism against alveolar flooding (see Fig. 44.11A). This clearance of fluid from the alveolar space may be accelerated by β -adrenergic agents (Frank et al., 2000) and by dopamine (Saldias et al., 1999). Whether these agents will have any clinical efficacy remains to be determined.

Symptoms of Pulmonary Edema

As discussed previously, fluid filtered into the alveolar interstitium ordinarily moves rapidly along pressure gradients into the extra-alveolar interstitium, where it is removed by the lymphatics. A delay in this process at birth can result in clinical transient respiratory distress. The first signs and symptoms of pulmonary edema are related to the presence of extra fluid in the interstitial cuffs of tissue that surround airways. As fluid builds up in these cuffs, airways are compressed, and infants develop signs of obstructive lung disease. The chest may appear hyperinflated, and auscultation reveals rales, rhonchi, and a prolonged expiration. Early in the course, chest radiographs reveal lung overinflation and an accumulation of fluid in the extra-alveolar interstitium—linear densities of fluid that extend from the hilum to the periphery of the lung (the so-called sunburst appearance) and fluid in the fissures. With more severe edema, fluffy densities appear throughout the lung as alveoli fill with fluid. Heart size may be increased in infants with edema from increased intravascular pressure. Initially, infants present with increased PaCO_2 secondary to impaired ventilation. Later PaO_2

decreases secondary to ventilation–perfusion mismatching and alveolar flooding. In adults a ratio of protein concentration in tracheal aspirate to that in plasma greater than 0.5 may help to differentiate permeability pulmonary edema from high-pressure pulmonary edema (Fein et al., 1979).

Treatment of Pulmonary Edema

Treatment of pulmonary edema is directed at relieving hypoxemia and lowering vascular pressures. Hypoxemia should be treated with the administration of oxygen and, if necessary, positive pressure ventilation. Positive end-expiratory pressure frequently increases oxygenation in individuals with pulmonary edema by improving ventilation–perfusion matching within the lung. Available evidence suggests that positive pressure ventilation does not reduce the rate of transvascular fluid filtration in the lung (Woolverton et al., 1978). Optimal treatment of pulmonary edema requires correction of the underlying cause. In infants with patent ductus arteriosus (Fig. 44.12) or other heart disease amenable to surgery, this is often easily accomplished. In cases of permeability edema or edema from nonsurgical heart defects, correction of the underlying cause may not be possible. In these instances the only remaining option is to lower vascular pressures (even in permeability edema, lowering vascular pressures lowers the rate of fluid filtration and may also improve lymphatic function). This can be accomplished by the lowering of circulating blood volume by use of diuretics and fluid restriction, by improvement of myocardial function with the use of digitalis or other inotropic agents, or in severe cases by use of a systemic vasodilator to reduce afterload and lower vascular pressures directly.

Neonatal Respiratory Therapy

EDUARDO BANCALARI, NELSON CLAURE, AND DEEPAK JAIN

KEY POINTS

- In addition to measurement of blood gases and oxygen saturation, determination of adequacy of ventilation in mechanically ventilated neonates consists of clinical assessment of chest expansion, breathing frequency, and breath sounds and may be complemented by the monitoring of tidal volume and minute ventilation with use of flow sensors.
- Strategies to avoid the harmful effects of hyperoxemia in preterm infants may have detrimental effects because of unintended hypoxemia.
- While the use of a high-flow nasal cannula in premature infants has increased because of ease of use, less risk of nares injury, and perceived improvement in patient comfort, there is little evidence of improved outcomes when compared with use of nasal continuous positive airway pressure.
- The decision to initiate invasive mechanical ventilation is usually based on gestational age, the severity of respiratory failure, the underlying disease process, the availability of noninvasive respiratory support alternatives, and the experience of the clinical team, the rate of complications, and patient outcomes.
- Metaanalyses comparing different volume-targeted ventilation strategies with pressure-limited ventilation favor the use of volume-targeted ventilation because of decreased duration of ventilation and decreased incidence of bronchopulmonary dysplasia, pneumothorax, and severe neurologic injury.
- Serious complications of mechanical ventilation include pulmonary gas leaks, airway damage, ventilator-associated pneumonia, and neurologic sequelae.
- Neonatal respiratory monitoring could be significantly improved by advances in noninvasive monitoring of arterial and venous blood gases and monitoring of brain and organ oxygenation, perfusion, and hemodynamics.

Respiratory Monitoring

One of the most important aspects of newborn intensive care is continuous monitoring of cardiorespiratory function, ventilation, and oxygenation. This can be accomplished by bedside monitoring devices and laboratory analysis. The information provided by these monitoring techniques is an essential tool in the diagnosis and treatment of respiratory problems in the newborn.

Breathing Frequency, Apnea, and Heart Rate Monitoring

Transthoracic impedance is the standard method used to monitor neonatal respiration. This technique is based on changes in the

thorax's electrical impedance caused by changes in gas volume during respiration measured by surface electrodes. Transthoracic impedance is mainly used to monitor breathing frequency and to detect apnea (Olsson and Victorin, 1970). Breathing is detected when the change in impedance exceeds a set threshold. A low threshold decreases sensitivity for apnea, and small disturbances such as cardiogenic oscillations can be falsely considered as breathing. Conversely, a high threshold may lead to false apnea alarms during shallow breathing. Monitors can automatically adjust this threshold or the impedance amplitude or use sophisticated methods for detecting breathing or apnea. Transthoracic impedance is not reliable in assessing absolute tidal volume (V_T), but it can be used to assess relative changes.

This technique is more effective in detecting apneas of central origin than obstructive apnea because the latter can produce internal displacement of gas volumes that still change impedance. More specific techniques are used for diagnosis and classification of apnea, including detection of gas exhalation by thermistors and CO_2 monitors and respiratory inductance plethysmography, which measures expansion of the chest and abdomen. Transthoracic impedance monitors can also measure heart rate and are used to detect bradycardia and tachycardia. More sophisticated devices or built-in algorithms are used to detect cardiac rhythm anomalies.

Ventilation Monitoring

The basic clinical determination of the adequacy of ventilation in the mechanically ventilated neonate consists of assessment of chest expansion, breathing frequency, and auscultation. This can be complemented by the monitoring of and minute ventilation with flow sensors available in most neonatal ventilators. This allows the monitoring of spontaneous breathing, assessment of respiratory system mechanics, and detection of excessive or insufficient V_T , hypoventilation, and gas trapping (Becker and Donn, 2007). These flow sensors are also used to synchronize positive pressure ventilation with the infant's spontaneous inspiration (discussed in detail later).

Flow sensors are classified as mainstream when they are connected between the endotracheal tube (ETT) and the ventilator circuit, also known as *proximal flow sensors*, or built into the ventilator. In small infants, mainstream flow sensors have better accuracy than those built into the ventilator because V_T and flow are only a fraction of the gas volumes compressed in the circuit and the circulating bias flow (Cannon et al., 2000; Chow et al., 2002). Although mainstream flow sensors are usually small and typically have a dead space volume of less than 1 mL, they can induce rebreathing of exhaled gases and affect CO_2 elimination in small preterm infants (Figueras et al., 1997; Claure et al., 2003).

Ventilation monitoring based on flow measurement has become the standard in modern neonatal ventilators, and monitoring of the adequacy of V_T has been shown useful in reducing the incidence of pneumothorax in preterm infants (Rosen et al., 1993; Vellanki et al., 2012). More recently V_T monitoring has also been shown to be useful in assessing ventilation during high-frequency ventilation (HFV) (Sturtz et al., 2008).

Blood Gas Monitoring

Blood Gas Sampling

Determination of arterial blood gas status is key to the management of respiratory failure and lung disease in the neonate. Measurements of arterial oxygen tension (PaO_2) and arterial carbon dioxide tension (PaCO_2) are considered the reference standard by which the efficacy and adequacy of ventilation and oxygenation are assessed.

To perform repeated arterial blood sampling, placement of invasive catheters is required. In neonates, umbilical artery catheters (UACs) are commonly used during the acute phases of respiratory failure. Samples obtained from a UAC are the most reliable when proper sample handling and laboratory procedures are followed. However, there are important issues that must be considered before their placement and during their use to ensure that the risk-to-benefit ratio remains favorable. UACs have risks during placement and use, including damage and perforation of the vessel, formation of thrombi and emboli, vasospasm, and infection. UAC lines with the tip above the celiac plexus are associated with fewer complications than those with the tip below the renal or mesenteric artery (Barrington, 2000).

Alternatively, percutaneous lines in the radial, ulnar, or dorsalis pedis artery can be used instead of a UAC. When an invasive line is not available, arterial blood can be obtained by puncture of peripheral arteries. The results should be interpreted carefully because the procedure frequently disturbs the infant and can alter blood gases. An alternative is to obtain blood samples from the peripheral capillary bed of the medial or lateral plantar surface. These are obtained after warming of the area, which produces hyperemia or “arterialization.” These samples provide an approximate estimate of arterial blood gases, and the results should also be interpreted cautiously (Courtney et al., 1990). This procedure can also disturb the infant and alter the basal status.

Errors in blood gas measurement are often technique related. Contamination by air bubbles or venous blood can alter the results. Contamination by fluids can reduce PO_2 and PCO_2 while also affecting pH. Because blood cell metabolism continues, reduction of the time from sampling to analysis and cold temperature storage and transport attenuate its effects.

During conditions such as transport or when the turnaround time is important, bedside portable blood analysis devices have proven to be most effective (Murthy et al., 1997). Another alternative measurement method is that of indwelling electrodes inserted through a UAC that provide continuous blood gas information, but they are not used in clinical practice (Rais-Bahrami et al., 2002). This is likely because of the need for an invasive catheter, which, in general, is avoided to reduce the risk of thrombus formation and bloodstream infections.

Transcutaneous Blood Gas Monitoring

Measurements of transcutaneous O_2 tension (TcPO_2) and transcutaneous CO_2 tension (TcPCO_2) provide a continuous noninvasive estimate of the composition of arterial blood gases. Local hyperperfusion of the skin induced by heating creates a skin–electrode unit

under the transcutaneous sensor, and electrochemical measurements in an electrolyte solution within this unit determine the partial pressure of O_2 and CO_2 .

Because skin metabolism continues, local hyperemia is needed to maintain skin perfusion sufficiently high so that the measured TcPO_2 is not affected by the skin's O_2 consumption. For this reason, the accuracy of TcPO_2 measurement depends on electrode temperature, with better accuracy at or above 43°C (Huch et al., 1976). Under adequate conditions, TcPO_2 correlates with PaO_2 (Peabody et al., 1978). However, conditions such as arterial hypotension and acidosis often result in underestimation because of insufficient skin perfusion (Versmold et al., 1979).

During TcPCO_2 measurement, CO_2 molecules diffusing from the capillary bed change the pH of the electrolyte solution in the skin–electrode unit. This changes the electric potential, which is then translated into TcPCO_2 . Metabolism in the skin produces CO_2 , and if the local perfusion is not adequate, the measured values can exceed those of PaCO_2 . TcPCO_2 measurements can also be affected by conditions affecting peripheral perfusion (Peabody and Emery, 1985) and tend to overestimate PaCO_2 in hypercapnia as local perfusion decreases (Martin et al., 1988).

Some reports have demonstrated improved TcPCO_2 measurement accuracy in preterm infants of less than 29 weeks' gestation but inconsistent precision because of large between-patient variability (Aliwalas et al., 2005; Bernet-Buettiker et al., 2005; Tingay et al., 2005). TcPCO_2 measurements have also been shown to be tightly correlated to capillary PCO_2 . Although capillary blood gases may not be the optimal reference, their use is often the only available method for long-term monitoring because indwelling lines are available only during the acute phase of respiratory failure. In preterm infants, TcPCO_2 may reduce the need for blood sampling and the number of painful punctures, but the main benefit is the ability of continuous monitoring. For this reason, TcPCO_2 measurement is commonly used as an adjunct to standard blood gas sampling to provide information on trends and respiratory stability. This is particularly useful in the management of invasive ventilatory support, where close tracking of the effects of ventilator changes is required.

The thin epidermal skin layer of the neonate has a relatively low metabolism. Nonetheless, some transcutaneous monitors include a metabolic correction factor. Measurements of TcPO_2 and TcPCO_2 require a period of stabilization after sensor application until skin perfusion increases. A tight seal around the skin–electrode unit is required for accuracy. Similarly to blood gas sampling, an air bubble between the skin and the electrode can lower TcPCO_2 and shift TcPO_2 toward the ambient partial O_2 pressure.

The transcutaneous electrode is usually applied on the thorax or the thigh. The need for high electrode temperature combined with the premature infant's skin sensitivity requires frequent change of the application site to avoid thermal injury. Transcutaneous measurements have an intrinsic delay of a few seconds with respect to changes occurring in the arterial blood.

End-Tidal Carbon Dioxide Monitoring

Monitoring of the partial pressure of CO_2 in end-tidal gases (PetCO_2) is based on the assumption that gases measured at the airway opening at the end of exhalation represent alveolar gases and that their levels match the arterial levels. PetCO_2 is measured by infrared sensors placed mainstream or by side-stream gas sampling. PetCO_2 measurements are dependent on V_T size because the exhaled gas has to carry alveolar gas. The accuracy of PetCO_2 measurement is affected by lung disease, with an increased arterial to alveolar CO_2

gradient resulting in underestimation of PaCO_2 (Sivan et al., 1992). For this reason, PetCO_2 is more often used in term or near-term neonates and pediatric patients who require CO_2 monitoring for reasons other than lung disease. Measurements of PetCO_2 in mechanically ventilated infants can be affected by gas leaks around the ETT. A way to circumvent this limitation is to sample exhaled gas from the distal end of a multilumen ETT (Kugelman et al., 2008), which has been shown to improve accuracy. This technique has been shown to be useful in improving the maintenance of PaCO_2 within the intended range in preterm infants (Kugelman et al., 2016).

Arterial Oxygen Saturation Measured by Pulse Oximetry

Estimation of the oxygen saturation in arterial blood (SaO_2) by pulse oximetry (SpO_2) is based on the differences in the rates of light absorption between oxygenated hemoglobin (Hb) and deoxygenated or reduced Hb in the red and infrared regions of the light spectrum. Deoxygenated Hb absorbs more red light and less infrared light than oxygenated Hb. As SaO_2 increases, the ratio of the absorption of red light to that of infrared light decreases. It is assumed that in the circulation, changes in this ratio can be produced only by pulsating arterial blood.

The amount of light absorbed by pulsatile blood is only a small fraction of the light absorbed by tissue and venous blood. Thus changes in pulse amplitude or patient movement that disrupt the optical pathway from the transmitter to the receiver side of the probe, or that produce venous blood fluctuations, can affect SpO_2 accuracy, although newer techniques have reduced the effect of the latter (Hay et al., 2002). The accuracy of SpO_2 is also affected by conditions such as low perfusion or by inappropriate placement, such as excessive tightening of the probe (Bucher et al., 1994).

In a prospective evaluation of the accuracy of SpO_2 in neonates, SpO_2 data were shown to be well correlated with measured SaO_2 (Hay et al., 1989). However, more recent retrospective studies that examined paired pulse oximetry and blood gas data documented in medical records suggested SpO_2 can overestimate arterial oxygen levels (Quine et al., 2009; Rosychuk et al., 2012). The accuracy and reliability of the current SpO_2 technology and the factors that affect them should be further examined in well-controlled prospective studies.

The use of pulse oximetry to avoid hyperoxemia and hypoxemia during oxygen supplementation must be done in the context of the sigmoid-shaped relationship between PaO_2 and SpO_2 . High SpO_2 levels are almost always induced by an excessive fraction of inspired oxygen (FIO_2), and although SpO_2 levels in the upper range can be associated with a wide range of PaO_2 (Brockway and Hay, 1998), data indicate that an SpO_2 threshold of 93% or 95% can be used to avoid most PaO_2 values greater than 80 mmHg (Hay et al., 1989; Poets et al., 1993; Bohnhorst et al., 2002; Castillo et al., 2008). On the other hand, most SpO_2 values below 80% are associated with PaO_2 below 40 mmHg. In this situation a moderate increase in supplemental oxygen is usually enough to correct the hypoxemia without inducing hyperoxemia.

Data indicate reliable detection of hypoxemia spells by pulse oximetry (Bohnhorst et al., 2000; Hay et al., 2002). Nonetheless, some hypoxemia episodes detected by pulse oximetry are deemed artifactual by the caregiver because of their temporal association with infant movement. However, these hypoxemia episodes may still need to be attended to in view of data showing increased infant activity leading to changes in heart rate, lung volume, and ventilation that trigger hypoxemia episodes (Bolivar et al., 1995; Dimaguila et al., 1997) and that hypoxemia episodes are more

frequent during periods when the infants are awake than when they are in active or quiet sleep (Lehtonen et al., 2002).

Oxygen Therapy

Principles

Neonates with acute respiratory failure or with some degree of respiratory distress experience abnormalities of gas exchange that almost invariably result in hypoxemia. Depending on the severity and duration of hypoxemia and the metabolic demands for oxygen, this can lead to reduced oxygen availability and tissue hypoxia. Hypoxemia in the neonate can result from reduced alveolar oxygen content, low ventilation-perfusion ratio, reduced diffusion capacity, and extrapulmonary right-to-left shunting.

The most common form of respiratory therapy for the neonate with hypoxemia consists of oxygen supplementation. A higher FIO_2 increases the alveolar O_2 tension (PAO_2) in both well-ventilated and partially ventilated areas of the lung. The resulting increase in the alveolar-arterial O_2 gradient in part compensates for the conditions producing hypoxemia mentioned earlier. The proportion of neonates requiring supplemental O_2 increases with lower gestational age because premature birth is associated with many of the factors that contribute to hypoxemia.

The primary goal of oxygen therapy is to maintain adequate oxygen availability to the tissues, especially to the central nervous system and the heart, and to improve an incomplete hemodynamic adaptation to extrauterine life evident by persistently elevated pulmonary vascular resistance and patency of the ductus arteriosus. These goals, however, need to be attained while minimizing the side effects of oxygen toxicity on the eye, brain, and other organs that are common in the premature infant.

Normal SaO_2 for room air-breathing term or healthy preterm infants is reportedly greater than 93%, with PaO_2 levels above 70 mmHg (Fenner et al., 1975; Richard et al., 1993; O'Brien et al., 2000). Maintenance of such oxygenation levels in premature infants with lung disease and immaturity would almost invariably require high inspired O_2 levels. Earlier strategies to "normalize" oxygenation with the use of high FIO_2 in this population resulted in high rates of retinopathy of prematurity (ROP) and blindness (Campbell, 1951; Crosse and Evans, 1952; Cross, 1973). Conversely, strict curtailment of supplemental O_2 regardless of the oxygenation level was associated with increased rates of neurologic damage and death (Patz et al., 1952; Avery, 1960; Bolton and Cross, 1974).

The preterm infant is at risk of O_2 -induced injury because of an immature antioxidant system that is unable to balance the oxidative effects of O_2 radicals. In the past, severe neonatal lung injury was only partly attributed to exposure to high FIO_2 . However, animal experiments have shown that lung damage was caused by high alveolar O_2 independent of PaO_2 (Northway et al., 1967; Miller et al., 1970; Taghizadeh and Reynolds, 1976). In preterm infants, hyperoxia has been linked to neurologic damage and impairment (Ahdab-Barmada et al., 1980; Collins et al., 2001; Haynes et al., 2003). For this reason, when supplemental O_2 is administered to hypoxemic neonates, oxygenation is continuously monitored to avoid hyperoxemia.

Methods of Administration

In neonates, supplemental O_2 is usually administered by means of a head box, mask, nasal cannula (NC), nasal continuous positive airway pressure (N-CPAP), or a mechanical ventilator. In

mechanically ventilated infants or in infants receiving N-CPAP, supplemental O₂ is administered by the mixture of air and O₂ in the ventilator or continuous positive airway pressure (CPAP) device. In all four methods, verification that the desired FIO₂ is delivered by means of an O₂ analyzer is recommended.

A head box, the least invasive of these methods, is generally used for infants who only need supplemental O₂. Depending on the size of the infant, a minimum flow is required to flush exhaled gases and minimize entrainment of ambient air. Gas warming and humidification are recommended to avoid drying of the airways and secretions as well as to avoid heat losses.

NCs deliver a constant flow of the air–O₂ mixture to the nostrils. The effective FIO₂ is determined by the delivered flow and the infant's inspiratory flow. With increasing flows the actual inspired O₂ concentration approaches that of the mixture delivered by the cannula, whereas higher inspiratory flows, in larger infants or during periods of increased demands, reduce the actual inspired O₂ by entraining more room air (Walsh et al., 2005). The actual FIO₂ during oral breathing has not been determined. Cannula flows greater than 1 L/min can produce positive pressure at the nose at levels similar to or above typical CPAP levels (Locke et al., 1993), which can become very high if the prongs fit tightly in the nostrils. Gas conditioning is recommended to avoid drying of the nose and mucosal damage (Kopelman and Holbert, 2003). NCs have gained popularity because they are flexible and facilitate access to and mobility of the infant.

Treatment Strategies

The effects of the introduction of continuous monitoring of oxygenation in the care of preterm infants in relation to ROP have been inconsistent (Bancalari et al., 1987; Grylack, 1987; Yamamoto et al., 1987). Data showing that ROP severity was associated with the duration of hyperoxemia emphasized the importance of oxygen monitoring and avoidance of hyperoxemia (Flynn et al., 1987). However, infants with severe ROP were also found to spend considerable periods in hypoxemia.

Continuous monitoring of arterial oxygen saturation by pulse oximetry (SpO₂) has become standard practice in neonatal intensive care. The use of SpO₂ has been extended to the delivery room for titration of FIO₂ during resuscitation (Escrig et al., 2008; Dawson et al., 2009). Although the optimal range of SpO₂ in premature infants has not been fully defined, existing data suggest deleterious effects of hyperoxemia, with higher rates of ROP and worse respiratory course in neonatal centers that have tolerant policies toward high SpO₂ levels (Tin et al., 2001; Anderson et al., 2004). Observational data indicate that more restrictive policies toward high SpO₂ can reduce the rates of ROP (Chow et al., 2003; Wright et al., 2006).

Tolerance of high SpO₂ levels in convalescent infants beyond the neonatal period has been proposed to improve growth and neurologic outcome, as well as to stop the progression of threshold ROP. However, clinical trials to test this showed minimal benefits that were outweighed by deterioration in lung function likely caused by the additional O₂ required to maintain higher SpO₂ (STOP-ROP Multicenter Study Group, 2000; Askie et al., 2003).

Implementation of policies to curb hyperoxemia should also consider the potential deleterious effects of insufficient oxygenation. Hypoxemia can increase patency of the ductus arteriosus (Skinner et al., 1999; Noori et al., 2009) as well as increase the resistance of the pulmonary vasculature and airways, particularly in infants with established lung disease (Cassin et al., 1964; Halliday et al.,

1980; Abman et al., 1985; Teague et al., 1988; Tay-Uyboco et al., 1989). Premature infants often experience hypoxemia in the form of spells. These spells increase in frequency with postnatal age and are more common in infants with chronic lung disease (Bolivar et al., 1995; Dimaguila et al., 1997; Garg et al., 1988; Di Fiore et al., 2010). Although most episodes are mild, some can be severe and prolonged. Frequent hypoxemia episodes and particularly those of long duration have been linked to increased incidence of severe ROP (Di Fiore et al., 2010). More recently, a post hoc analysis of the Canadian Oxygen Trial revealed an association between prolonged hypoxemia episodes and neurodevelopmental impairment (NDI) (Poets et al., 2015).

The goal of oxygen supplementation is to maintain adequate oxygenation while minimizing hyperoxemia and oxygen exposure. To achieve this, FIO₂ is adjusted to keep SpO₂ within a target range and avoid exposure to extreme high and low levels. However this is only partially achieved during routine care. A multicenter study showed that preterm infants receiving supplemental oxygen spent only half of the time with SpO₂ within the target range, more than one-third of the time with SpO₂ above the target range, and almost one-fifth of the time with SpO₂ below the target range (Hagadorn et al., 2006; Lupton et al., 2006; Lim et al., 2014). This is due to their oxygenation instability and frequent stimulation related to routine neonatal care.

In preterm infants the stability of oxygenation can be influenced by the target range of SpO₂. Relatively small decreases in the target range can produce significant increases in the proportion of time spent with SpO₂ below 80% or 85% (McEvoy et al., 1993; Lupton et al., 2006). This is in agreement with data from the Surfactant, Positive Pressure, and Oxygenation Randomized Trial (SUPPORT), where the frequency of hypoxemia spells was higher among infants assigned to the 85% to 89% target range compared with the 91% to 95% target range (Di Fiore et al., 2012). These hypoxemia episodes often require a transient increase in FIO₂, but a delayed response can prolong the hypoxemia, whereas a delayed reduction of FIO₂ after hypoxemia ends can induce hyperoxemia. Caregivers often tolerate or maintain high SpO₂ levels with the purpose of reducing the frequency of the spells or attenuating their severity (Claure et al., 2009, 2011; Van Zanten et al., 2014). When FIO₂ is increased in response to a hypoxemia spell, SpO₂ should be continuously observed, and FIO₂ should be reduced as the spell resolves. In clinical practice this is not always the case, and many infants experience hyperoxemia because FIO₂ is not quickly returned to the basal level when the hypoxemia ends (Van Zanten et al., 2014). This exposure to high saturations can further increase the risk of ROP (McColm et al., 2004). Neonatal center policies should clearly define the response of the caregiver to these events to minimize both excessive and inadequate oxygenation.

In recent years clinicians targeted progressively lower SpO₂ in preterm infants to reduce the complications associated with hyperoxemia and oxygen exposure. This was mainly driven by observational data that showed that policies targeting low SpO₂ ranges were associated with better outcomes (Chow et al., 2003; Wright et al., 2006). However, it is unknown how closely such ranges were actually maintained. Multiple clinical trials have been conducted to determine if targeting SpO₂ in the lower portion (85%–89%) versus the upper portion (91%–95%) of the commonly accepted range of 85% to 95% would reduce ROP and improve neurologic outcome. SUPPORT and the Benefits of Oxygen Saturation Targeting II (BOOST II) trials showed that targeting the 85% to 89% range reduced the rate of severe ROP compared with targeting the 91% to 95% range (SUPPORT Study Group

of the Eunice Kennedy Shriver NICHD Neonatal Research Network 2010a; Stenson et al., 2011). Unexpectedly, these trials showed higher mortality among infants assigned to the lower SpO₂ range. In contrast, in the Canadian Oxygen Trial, mortality and severe ROP did not differ significantly between the two SpO₂ target ranges (Schmidt et al., 2013). In these trials the actual SpO₂ levels achieved by manual titration of FiO₂ did not exactly match the assigned targets. The exposure to very high SpO₂ was greater with the higher target range, and there was a greater exposure to very low SpO₂ with the lower range.

These data suggest that strategies to avoid the harmful effects of hyperoxemia in preterm infants may have detrimental effects due to the unintended hypoxemia. This underlines the importance of striking a balance between avoidance of oxygen toxicity and possible hypoxemia to avoid long-term complications in this vulnerable population.

Automated systems to adjust the inspired oxygen to maintain SpO₂ within a target range have been developed for use in neonates. Short-term studies showed consistent improvement in the maintenance of SpO₂ within the target range as well as reductions in hyperoxemia, severe hypoxemia episodes, oxygen exposure, and staff workload with these automated systems compared with manual adjustments by the clinical staff or by a caregiver fully dedicated to this task (Claure et al., 2001; Urschitz et al., 2004; Claure et al., 2009; Morozoff et al., 2009; Claure et al., 2011; Hallenberger et al., 2014; Zapata et al., 2014; Claure et al., 2015; Lal et al., 2015; van Kaam et al., 2015; Waitz et al., 2015). Large trials are needed to determine the effects of extended use of automatic FiO₂ control on short-term and long-term neonatal outcomes.

Policies of oxygenation monitoring should clearly identify both the intended range and the alarm limits of SpO₂, and sufficient staff must be allocated to achieve this task. Setting SpO₂ alarm limits near or at the limits of the prescribed target range increases the proportion of time premature infants spent within the target (Hagadorn et al., 2006). Maintenance of SpO₂ within the target range can be affected by staff limitations during routine clinical care (Sink et al., 2011; Lim et al., 2014). Staff compliance with SpO₂ alarms plays an important role in keeping the target, but frequently the high SpO₂ alarm level is increased to reduce the number of alarms (Clucas et al., 2007). Insufficient staff education and communication can also influence the maintenance of SpO₂ within the intended range. A survey showed that only one-third of the caregivers were aware of and could identify their center's oxygenation policies (Nghiem et al., 2008), while a concerted effort involving protocol development and staff training showed clear improvements in SpO₂ targeting (Ford et al., 2006). These efforts can include the use of SpO₂ histograms to monitor compliance with the target range (Bizzarro et al., 2014). All these initiatives must, however, consider the potential for reduced staff attentiveness to SpO₂ alarms and alarm fatigue, which may be particularly important when SpO₂ target or alarm limits are changed (Ketko et al., 2015).

Policies for SpO₂ targeting at the time preterm infants reach near-term postmenstrual age (e.g., 36 weeks' postmenstrual age) can differ significantly between centers, and this can influence the classification of bronchopulmonary dysplasia (BPD) (Ellsburly et al., 2002). This is because BPD classification is commonly based on the need for supplemental oxygen. Centers with policies that target higher SpO₂ have greater proportions of infants receiving supplemental O₂, and many of those infants need not receive supplemental O₂ if lower SpO₂ levels are tolerated and if their actual needs are

monitored closely (Walsh et al., 2004). This is also the case at the time of discharge and during home oxygen therapy.

Noninvasive Respiratory Support

Because of the severe complications associated with invasive mechanical ventilation, there has been a persistent search for less invasive alternatives to support infants with respiratory failure. This is especially relevant in the small preterm infant, who is more susceptible to acute complications and chronic pulmonary sequelae. The strategies that have shown themselves to be most clinically effective are use of N-CPAP, nasal intermittent positive pressure ventilation (IPPV), and, more recently, a high-flow NC (HFNC). These strategies can be used to support infants with respiratory failure in lieu of invasive mechanical ventilation.

Nasal Continuous Positive Airway Pressure

Use of CPAP was introduced in 1971 by George Gregory to stabilize lung volume in preterm infants with respiratory distress syndrome (RDS) (Gregory et al., 1971). Initially, the pressure was delivered through a mask or head box and later was applied through nasal prongs. With the introduction of surfactant therapy, more infants were intubated and treated with mechanical ventilation, and the use of N-CPAP declined for several years; in the past decade, however, it has been reintroduced as a safe alternative to mechanical ventilation.

The physiologic effects of N-CPAP include prevention of alveolar collapse and stabilization of the functional residual capacity (FRC), thereby reducing pulmonary shunts and resulting in better oxygenation. N-CPAP also stabilizes large and small airways and can decrease the work of breathing and obstructive apnea episodes. By preventing alveolar closure and reopening with each breath, N-CPAP can preserve surfactant function.

N-CPAP is used primarily in infants with RDS who because of surfactant deficiency have decreased FRC. N-CPAP is effective during the transition period immediately after birth while reabsorption of fetal lung fluid and establishment of FRC are occurring. It is also used for reducing frequency and severity of apneic episodes and in stabilizing respiratory function after extubation (Locke et al., 1991) and in infants with airway obstruction. The application of continuous distending pressure during use of N-CPAP can be beneficial in infants with increased pulmonary blood flow and pulmonary edema secondary to heart lesions with left-to-right shunting such as patent ductus arteriosus.

As mentioned earlier, the major indication for N-CPAP use in preterm infants is RDS. In recent years most centers have used N-CPAP soon after birth in infants who have sufficient respiratory drive. The exceptions are infants who are depressed at birth or those who have severe respiratory failure and are intubated to administer surfactant. The success rate with use of CPAP soon after birth depends on the maturity of the infant and the severity of the respiratory failure, but more than 50% of preterm infants who are not depressed at birth can be managed successfully with N-CPAP, avoiding the use of invasive ventilation (Kamper and Ringsted, 1990; Dani et al., 2004; Ammari et al., 2005; Reininger et al., 2005). The sooner N-CPAP therapy is started, the better the results are in infants with RDS (Hegyi and Hiatt, 1981; Gittermann et al., 1997; Jonsson et al., 1997; Verder et al., 1999). There is some evidence that early use of N-CPAP instead of invasive ventilation could lead to a small reduction in the incidence of BPD (Morley et al., 2008; SUPPORT Study Group of the Eunice

Kennedy Shriver NICHD Neonatal Research Network, 2010b; Schmolzer et al., 2013).

The other frequent indication for use of N-CPAP is to stabilize respiratory function after the infant has been weaned off mechanical ventilation and extubation. Although it is not clear whether the use of N-CPAP in this situation reduces the need for reintubation, it clearly prevents a deterioration of respiratory function (Davis and Henderson-Smart, 1999; Peake et al., 2005).

The levels of N-CPAP that are used in clinical practice range from 3 to 8 cmH₂O, with evidence of the higher end of this range being more effective in preventing extubation failure in preterm infants who still need supplemental oxygen at the time of extubation (Buzzella et al., 2014). These findings indicate beneficial effects of the higher distending pressure and improved stability of lung volume in infants with residual lung disease.

In practice, the level of N-CPAP used is determined by the severity of the lung disease, reflected by the inspired oxygen concentration and the degree of lung expansion in the chest radiograph. The more severe the disease is, the higher the level of N-CPAP that is used. As the respiratory condition improves and the oxygen requirement decreases, the level of N-CPAP is reduced to 3 to 4 cmH₂O before the prongs are removed.

Devices for Application of Nasal Continuous Positive Airway Pressure

N-CPAP has been applied with use of a variety of systems and devices. Most of the evidence suggests that the best results are obtained with double short nasal prongs (De Paoli et al., 2002). The devices used to generate the pressure can be a water column such as the one used for “bubble CPAP” or an adjustable valve at the end of a continuous-flow system or a variable-flow system. Although there are data suggesting that some of these systems are superior to others, in clinical practice the stability and permeability of the nasal interface are probably the most important factors determining the success or failure of this form of respiratory support. Recently, NCs have been used as a method for generating N-CPAP. The limitation of this method is that it is difficult to control and measure the actual pressures and inspired oxygen concentrations that are delivered to the infant because both depend on the gas flow and the leaks around the cannulas and through the mouth.

Complications

The complications of N-CPAP can be related to the pressure that is applied or to the interface with the nose. The application of excessive pressure can cause overdistension and alveolar rupture with pulmonary interstitial emphysema (PIE) and pneumothorax. It can also reduce venous return, increase pulmonary vascular resistance, and reduce cardiac output. Overdistension of the lung can also reduce compliance and induce hypoventilation.

When the nasal prongs are too large or are applied with too much pressure over the nasal septum, they can produce erosions or pressure necrosis that sometimes requires the interruption of the N-CPAP. Avoiding these complications and keeping the nasal prongs in place is a task that requires considerable time and skill. During application of N-CPAP there is a risk of gas being pushed into the stomach. A nasogastric catheter is often used to avoid excessive accumulation of gas and gastric distention.

Noninvasive Ventilation

IPPV via nasal devices was among the original forms of support used in preterm infants in respiratory failure (Llewellyn et al.,

1970). Recently, it has been reintroduced in neonatal care for indications including respiratory distress and apnea and to facilitate weaning of neonates off invasive mechanical ventilation. Noninvasive ventilation (NIV) consists in the application of intermittent positive pressure at the nose or upper airway. The resurgence of the use of NIV in preterm infants is largely because N-CPAP that is effective in improving gas exchange by stabilizing lung volume and the airways is not fully effective in maintaining ventilation in infants with weak inspiratory effort and inconsistent respiratory drive.

In infants with apnea, the cycling positive pressure at the upper airway may produce an intermittent stimulus that prevents or attenuates the duration of breathing pauses of central origin. In infants with central apnea, resumption of breathing following ventilator cycles has been described, and the reduction of apnea in comparison with use of N-CPAP is more striking among infants with more frequent apnea spells (Ryan et al., 1989; Lin et al., 1998; Bisceglia et al., 2007).

NIV can improve gas exchange and ventilation compared with N-CPAP in infants with respiratory insufficiency during the first few hours after birth as well as during their weaning off mechanical ventilation (Moretti et al., 1999; Bisceglia et al., 2007). In contrast, infants with mild respiratory distress who are stable while receiving N-CPAP and are able to maintain adequate gas exchange reduced their spontaneous breathing effort only when receiving NIV (Aghai et al., 2006; Ali et al., 2007; Chang et al., 2011). In the preterm infant the chest wall is excessively compliant, and the breathing effort is in part dissipated by an inward motion of the chest. Hence the reduced breathing effort with NIV can also be explained by a reduction in chest distortion (Kiciman et al., 1998; Ali et al., 2007).

In spite of the application of cycles of relatively small positive pressure, bilevel positive airway pressure (Bi-PAP) can increase CO₂ elimination and oxygenation (Migliori et al., 2005) compared with N-CPAP. Noninvasive HFV has been used and was shown to be useful as a rescue for avoidance of intubation in a group of infants in whom use of N-CPAP failed (van der Hoeven et al., 1998; Fischer et al., 2015).

In addition to the effects on apnea, ventilation, and breathing effort, it is possible that the increase in mean airway pressure during NIV can better maintain lung volume than can N-CPAP alone. It is also possible that CO₂ removal is increased during NIV by clearance of exhaled gases from the upper airway.

The use of NIV to achieve a reduction in the need for intubation or the duration of invasive mechanical ventilation is aimed at reducing the associated risks of lung injury. This is obviously more relevant in the smaller and more immature infants in whom use of N-CPAP more frequently fails. In infants with RDS, nasally delivered intermittent mandatory ventilation (IMV) has been shown to reduce the need for invasive ventilation early in life (Kugelman et al., 2007; Meneses et al., 2011, 2012) and facilitate early extubation after surfactant administration (Bhandari et al., 2007). In some of these trials, NIV reduced incidence of BPD appreciably, but this was not a consistent finding. The possible long-term beneficial effects of nasal ventilation during the initial respiratory failure still need to be confirmed.

During weaning of infants off mechanical ventilation, adequate maintenance of lung volume is often achieved by use of N-CPAP. However, this fails in many infants because of insufficient ventilation resulting from central apnea, a weak respiratory pump, or poor lung mechanics due to the underlying lung disease. NIV has consistently been shown to be an effective way to reduce extubation failure (Friedlich et al., 1999; Barrington et al., 2001; Khalaf et al., 2001; Moretti et al., 2008), mainly by reducing apnea and

improving gas exchange. Smaller infants and those with poor lung function at extubation were more likely to benefit from nasal ventilation than larger infants or infants with better lung function (Khalaf et al., 2001).

The devices used for neonatal noninvasive positive pressure ventilation consist of conventional time-cycled pressure-limited ventilators that use the same circuits and gas-conditioning devices used for invasive ventilation, with the main difference being that in lieu of the ETT, positive pressure is applied through the same interfaces used for application of N-CPAP.

Synchronization of Noninvasive Ventilation

Noninvasive positive pressure can be delivered in the IMV mode, where the positive pressure cycles are delivered at fixed intervals. In some ventilators, ventilator cycles can be synchronized to the neonate's inspiration to provide nasal synchronized IMV (SIMV). Synchronized NIV can also be provided in the assist/control (A/C) and pressure support modes to assist every spontaneous inspiration.

The most frequently reported method for synchronization in NIV is the Graseby pressure capsule placed on the abdomen, but this system is no longer available in the United States (Friedlich et al., 1999; Barrington et al., 2001; Khalaf et al., 2001; Bhandari et al., 2007). Another method of synchronization is by detection of spontaneous inspiratory flow of the patient by use of mainstream flow sensors. However, large and variable gas leaks around the interface and the mouth may result in the risk of autocycling of the ventilator. Although this leak can be compensated by automatic adjustment of the flow trigger threshold in the ventilator, the efficacy of this mechanism in neonates has not been fully evaluated. One of the newer methods for synchronization is neurally adjusted ventilatory assist (NAVA), which uses the electrical activity of the diaphragm during inspiration to determine the timing and magnitude of the delivered pressure. Although this method has the advantage of not being affected by leaks and of achieving an early response to spontaneous inspiratory effort (Beck et al., 2009; Lee et al., 2015), further studies are needed to evaluate the impact of noninvasive use of NAVA in preterm infants.

Devices that alternate between two levels of positive airway pressure (Bi-PAP) are also available. In these devices the increase in pressure is achieved by an increase in circulating flow instead of a valve. For this reason, with Bi-PAP devices the increase in pressure may not be as fast or large as with conventional ventilators. Some Bi-PAP devices are capable of synchronizing the increase in airway pressure with the infant's inspiration using the Graseby capsule, but these devices are not available in all countries.

Ventilator cycles delivered at fixed intervals can fall toward the end of spontaneous inspiration or during exhalation and disturb the infant's breathing pattern, whereas delivery of the ventilator cycle when the upper airway is patent may increase transmission of the pressure and reduce the risk of gas being pushed into the esophagus. Nonsynchronized and synchronized modes of nasal ventilation have both been shown to be more effective than N-CPAP, but data are lacking on the superiority of synchronization in terms of efficacy or safety. Data on the most effective mode, frequency, and duration of the cycle and, most importantly, peak pressures during NIV are also lacking. Until more data are available a conservative approach with relatively low ventilator settings and in ranges near those used for intubated infants recovering from RDS or near extubation is recommended. This is particularly important in the setting of peak pressures, because V_T monitoring is not available during NIV.

Potential Drawbacks

The risk of gastrointestinal distention may be higher during NIV than during the use of N-CPAP because of the positive pressure cycles. However, clinical trials have not confirmed this.

There may also be some risk of pneumothorax and PIE during NIV as compared with the use of N-CPAP. Although there are no data on these side effects, caution should be exercised, and high peak pressures or ventilator rates should be avoided.

The risks of nasal damage and obstruction often observed during use of N-CPAP are also present in NIV. Proper application and maintenance of the nasal interface and avoidance of excessive force on the nasal septum are important to avoid these complications.

High-Flow Nasal Cannula

Traditionally, NC devices were used to deliver supplemental oxygen, but more recently they have been used to deliver continuous distending pressure as well (Sreenan et al., 2001). The pressure generated by the nasal cannula is dependent on the flow rate and the fit of the nasal cannula to the nares. As opposed to a regular NC, an HFNC uses heated and humidified gas at flow rates ranging from 2 to 8 L/min. In addition to continuous distending pressure, dead space washout from the HFNC may contribute to the increased gas exchange.

Use of an HFNC in preterm infants has increased significantly over the last decade with little evidence of improved outcomes when compared to CPAP (Shetty et al., 2016). The increased usage is largely due to ease of use, less risk of injury to nares, and increased patient comfort with use of an HFNC.

The most studied clinical application of an HFNC has been as respiratory support after extubation in preterm infants. In comparison with CPAP, trials have shown higher extubation failure rates and less nasal damage with HFNC (Collins et al., 2013; Manley et al., 2013; Wilkinson et al., 2016).

The effect of an HFNC has been evaluated as a primary form of respiratory support in preterm infants of 28 weeks' gestational age or more. Compared with use of N-CPAP, use of an HFNC resulted in similar failure rates or need for intubation (Yoder et al., 2013), but a more recent larger multicenter trial showed higher rates of failure and intubation with use of an HFNC (Roberts et al., 2016).

Drawbacks

One of the main concerns with use of an HFNC is lack of control and variability in distending pressure, leading to risk of excessive airway pressure and air leaks. The correct NC size and close monitoring of the position of the NC are both crucial to avoid these complications.

Invasive Mechanical Ventilation

Mechanical ventilation has been one of the main therapies contributing to the progress in neonatal critical care. This is especially relevant in the more immature infants who, besides lung immaturity, have a weak respiratory pump and poor central respiratory drive, making the need for mechanical ventilation very common.

Indications

The decision to initiate invasive mechanical ventilation in the newborn is very important because of the serious complications

associated with this mode of therapy and because in smaller infants it is often difficult to wean them off respiratory support. There is considerable variation between different centers in the criteria used to initiate mechanical ventilation. Most often, this decision is based on the gestational age of the infant, the severity of the respiratory failure, and the disease process that is underlying the respiratory failure. This is also done considering the alternatives available to support the infant's respiratory function. The experience of the team and the outcomes of infants exposed to mechanical ventilation in each institution should also be an important consideration. In units with vast experience and good outcomes, invasive mechanical ventilation may be used more liberally, whereas in units with limited experience and high rates of complications, other alternatives should be considered before they embark on invasive ventilation.

The decision to initiate mechanical ventilation is usually based on the clinical condition of the infant and the evaluation of arterial blood gases. In the preterm infant, mechanical ventilation is frequently started because of recurrent episodes of apnea and hypoxemia that require intervention for the infant to recover from them. In more immature infants, ventilation is often begun in the delivery room because of severe respiratory depression and bradycardia not responsive to stimulation. The other indication for mechanical ventilation is when PaCO_2 levels rise rapidly, indicating alveolar hypoventilation. Although there are no specific PaCO_2 levels, most clinicians initiate mechanical ventilation when PaCO_2 rises acutely above 55 to 65 mmHg and the pH decreases below 7.25 to 7.20.

The introduction of IPPV may result in a transient improvement in gas exchange, but prolonged invasive ventilation frequently results in further deterioration in pulmonary function because of the negative effects of high inspired oxygen concentrations, ventilator-associated infections, and overdistension of the lung. The effectiveness of mechanical ventilation is primarily due to the support of the infant's failing respiratory pump and the reduction in the work of breathing. One exception to this is the infant with RDS, in whom the positive airway pressure produces recruitment of distal air spaces, with improvement in ventilation-perfusion matching and gas exchange.

In other instances, mechanical ventilation is started because of hypoxemia not responsive to N-CPAP. Although there are no set levels of PaO_2 or FIO_2 to start ventilation in preterm infants with RDS, the initiation of mechanical ventilation is frequently associated with the decision to administer exogenous surfactant. The indications for surfactant differ between institutions, but there is good evidence that early administration of surfactant results in better outcomes, and therefore in an infant with RDS, surfactant is usually given when the inspired oxygen concentration required to maintain acceptable O_2 saturation levels increases above 30% to 40%. If the infant has hypercapnia or clinical signs of significant distress and impending failure, ventilation may be started earlier. In some centers, surfactant is given as prophylaxis to infants below a certain gestational age, usually 28 weeks. After the infant becomes more stable, he or she is extubated to N-CPAP.

In term infants, the indication for mechanical ventilation is usually more conservative because these infants are better able to cope with increased work of breathing. The indication also differs depending on the underlying cause of the respiratory failure. For example, in an infant with respiratory failure due to a congenital diaphragmatic hernia, ventilation is usually started immediately after birth, whereas in an infant with a congenital pneumonia or meconium aspiration, a more expectant approach can be taken,

and ventilation may not be started until there is evidence of rising PaCO_2 and hypoxemia requiring inspired oxygen concentrations up to 40% to 60%. A careful and continuous assessment of the infant is critical in deciding whether invasive ventilation should be started or not.

Inspired Gas Conditioning

During normal breathing, inspired gas is heated and humidified in the nasal passages and upper airways. By the time it reaches the distal airways, it is fully saturated with water vapor at core body temperature (i.e., 100% relative humidity at 37°C for an absolute humidity of 44 mg H_2O per liter of gas). The isothermal saturation point region in the respiratory tract, where the temperature of inspired gas equilibrates with core body temperature and the inspired gas is fully saturated, is near the main bronchi. As inspiratory flow increases, this point moves distally into the airways.

The nose and airways function as heat and moisture exchangers. There, a portion of heat and water added to the inspired gas is recovered during exhalation, with the net loss depending on the temperature and relative humidity of the gas. This requires continuous replenishment of water to the aqueous mucosal layer by the airway epithelium and loss of heat. In contrast to ambient air at 22°C and 50% saturated (absolute humidity of 9.7 mg H_2O per liter of gas) medical gases are typically colder ($\leq 15^\circ\text{C}$) and dry ($< 2\%$ relative humidity) and therefore require more heat energy and humidity. Hence all forms of respiratory support where medical gases are used require conditioning of the inspired gas. This is a key component of mechanical ventilation because the ETT bypasses the nose and upper airway.

Inadequate conditioning of the inspired gas can increase water and heat loss (Fonkalsrud et al., 1980). Exposure to dry and cold inspired gas can also produce inflammation of the airway epithelium and increase the risk of airway damage (Marfatia et al., 1975; Todd et al., 1991). Insufficient humidification can also affect the mucociliary transport system, reducing clearance of secretions, pathogens, and foreign particles as well as increase the risk of airway blockage by mucus plugs (Fonkalsrud et al., 1975). These effects are likely to be more striking in small infants, infants with impaired thermoregulation, and those who are fluid and energy limited. In small preterm infants, a few minutes of mechanical ventilation with inadequately conditioned gases can increase airway resistance and reduce lung compliance (Greenspan et al., 1991). Inadequate gas conditioning has also been associated with increased risk of air leaks and augmented need for O_2 (Tarnow-Mordi et al., 1989).

The standard method for conditioning of the inspired gases consists of a heater/humidifier device and heated breathing circuits. Dry and cold medical gases are heated in the heater/humidifier chamber to 37°C to increase the water-carrying capacity to 44 mg per liter of gas at 100% relative humidity. The gas travels through the ventilator circuit, where it is heated to 39°C to prevent condensation. The gas temperature decreases as the gas travels through the ETT, and gas is delivered at approximately 37°C and near 100% saturated at the distal end.

Many conditions can affect gas conditioning. Air temperature in an incubator or radiant warmer above the 39°C setpoint can inadvertently reduce heating at the ventilator circuit and result in condensation. To avoid this, the temperature probe can be insulated or placed outside the incubator or radiant warmer. If gas heating at the ventilator circuit is not adequate, low ambient temperatures and low circulating gas flows can also produce condensation. In general, the presence of water condensate in the ventilator circuit

and minimal consumption of the humidifier water indicate inadequate conditioning of the gas. Water condensation can occur in the ETT and connector when the incubator temperature is low and can result in water droplets being pushed into the airway.

The humidity of the inspired gas can also be increased by water nebulization. In contrast to the size of the water vapor molecules ($0.0001\ \mu\text{m}$), the size of aerosolized water particles ranges between 0.5 and $5\ \mu\text{m}$, which is large enough to potentially transport viruses or bacteria. Thus water nebulization is not an efficient or safe method, particularly for prolonged use.

Gas conditioning is also recommended during use of N-CPAP or nasal ventilation and oxygen head box or NC use because the nasal passages and airways may not achieve adequate conditioning of the cold and dry medical gases. These gases are typically heated to 32°C , but heating at or above room temperature may be sufficient. On the other hand, passing the gas through a water bath may not produce a sufficient gain in humidity because of the low water-carrying capacity of cold gas. Thick and dry nasal mucus and airway secretions are observed when gas conditioning is insufficient. Lack of conditioning may also affect body temperature and increase water losses.

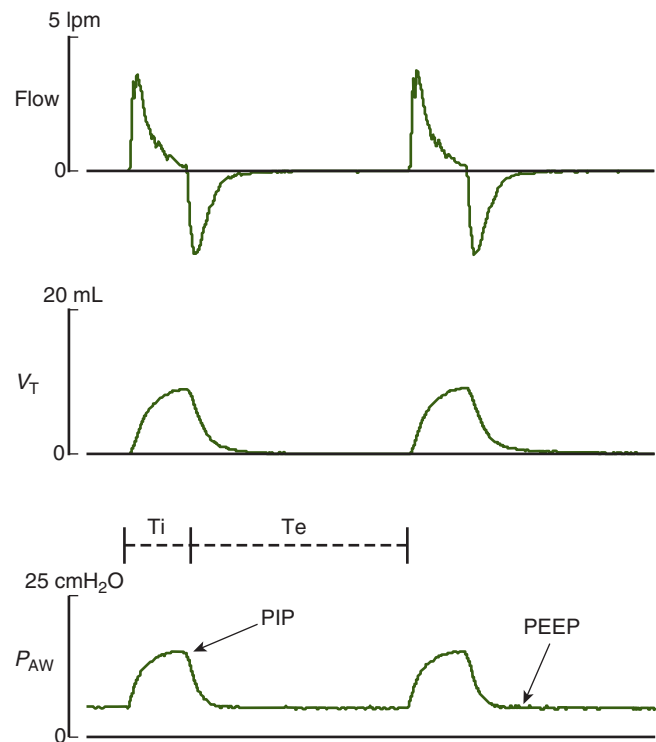

Conventional Positive Pressure Ventilation

Principles

IPPV can be described in its basic form as the cycled application of two different levels of positive pressure at the infant's airway. The positive end-expiratory pressure (PEEP) provides a continuous distending pressure to the lung and is aimed at maintaining lung volume. This is important because the ETT bypasses the upper airway mechanism that normally prevents lung volume loss by active closure of the glottis. The positive pressure applied at the airway opening is intermittently increased to a predetermined peak inspiratory pressure (PIP) during a set inspiratory time (T_i). The rise in airway pressure produces a gradient with respect to the alveolar pressure that drives a V_T of gas into the lung. This form of ventilation is known as *time-cycled pressure-limited ventilation*.

Neonatal ventilators use a constant flow of conditioned gas, also known as *bias flow*, through the breathing circuit to produce positive pressure. A controlled obstruction by a valve at the expiratory port of the ventilator produces PEEP and the intermittent increase to PIP at intervals determined by the set expiratory time (T_e) as shown in Fig. 45.1.

The circulating gas flow determines the profile of the increase in airway pressure by modulating the rise to the set PIP. The airway pressure rise is faster, and PIP is reached earlier at higher circulating flow rates. A fraction of this bias flow is driven into the infant's airways during tidal inflation. The infant's inspiratory flow, which indicates how fast the lung is being inflated, is in part determined by the profile of the airway pressure. The rapid rise in airway pressure produces a rapid increase in the infant's inspiratory flow to a high peak inspiratory flow that decays as the lung is inflated. In this pattern of rapid lung inflation, most of the V_T is delivered early in the inspiratory phase, as shown in Fig. 45.2. In contrast, a slowly rising airway pressure produces a slower inflation and a smaller peak inspiratory flow. A low bias flow may not be sufficient to reach the set PIP within a fixed T_i and in consequence produces a smaller V_T , also shown in Fig. 45.2. In older neonatal ventilators, the bias flow is constant during both the inspiratory phase and the expiratory phase, whereas newer ventilators self-adjust the flow necessary to produce a desired profile. In some ventilators the caregiver can set a maximal flow to be delivered by

• **Fig. 45.1** Time-Cycled Pressure-Limited Ventilation. Recordings of flow, tidal volume (V_T), and airway pressure (P_{AW}) showing that ventilator cycles, occurring at intervals determined by the expiratory time (T_e), increase the airway pressure from the positive end-expiratory pressure (PEEP) to the peak inspiratory pressure (PIP) during the set inspiratory time (T_i). The increase in pressure with respect to the alveolar pressure drives gas into the lung to achieve V_T . The inspiratory flow, which determines the rate of lung inflation, peaks initially and subsequently declines to zero as the lung is inflated. *lpm*, Liters per minute.

the ventilator to the circuit during the cycle, which also modifies the airway pressure profile.

The bias flow should be sufficient to sustain the PEEP when the infant's spontaneous respiratory flow demands increase. Otherwise, it may create an inspiratory load that the infant has to overcome with each breath. This is noted as a decline in PEEP during spontaneous inspiration that can even become negative. The bias flow is also responsible for removal of exhaled gases, and an insufficient bias flow may cause rebreathing. On the other hand, a very high bias flow produces an almost square inspiratory airway pressure waveform that increases the velocity of lung inflation. This may have undesirable consequences because the lung will be expanded much faster than during a normal physiologic inflation. In general, circulating bias flow rates for ventilated preterm infants are set between 5 and 8 L/min, with higher circulating flow rate settings necessary to accommodate gas leaks around the tube or the inspiratory demands of larger neonates.

The neonate's respiratory system mechanical properties (i.e., compliance and airway resistance) determine its time constant as their product. The respiratory time constant, which is a measure of the time to achieve equilibrium between the applied pressure and the alveolar pressure, differs with different lung diseases and their severity.

The compliance of the respiratory system (CRS) is a measure of the recoil pressure that opposes expansion and is determined by the compliance of lung and the compliance of the chest wall.

• **Fig. 45.2** Effect of Circulating Bias Flow. Recordings of flow, tidal volume (V_T), and airway pressure (P_{AW}) showing how increasing bias flow rates in the ventilator circuit change the profile of the airway pressure, with a more rapid rise toward the peak pressure. This produces a higher peak flow, which indicates faster lung inflation. An insufficient bias flow rate does not permit the generation of the desired peak pressure with each ventilator cycle and results in a smaller V_T . *lpm*, Liters per minute.

In the neonate, and most particularly in the preterm infant, CRS is mainly determined by the compliance of the lung because the chest wall is highly distensible. Lung diseases characterized by lung restriction, such as RDS, where the increased lung recoil is indicated by a low CRS and a short time constant, are quite prevalent in preterm infants. In addition, they have a respiratory pump that is often too weak to generate the pressure required to achieve an adequate V_T , and thus they require mechanical ventilation.

During positive pressure ventilation, a decreased CRS is characterized by a smaller V_T for a given transpulmonary pressure and a relatively brief duration of inflation. As shown in Fig. 45.3, the shorter time constant is illustrated by a shorter duration of inflation with an earlier return of the inspiratory flow to zero. This marks the point when the airway and alveolar pressures are at equilibrium. At this point, the PIP equals the lung's recoil pressure, with CRS as the ratio between the V_T and the applied pressure. When CRS decreases, prolonging the T_i is ineffective, and a higher PIP is required to maintain a constant V_T .

The resistance of the airways opposes the flow of gas, which dissipates part of the driving pressure during lung inflation. In diseases characterized by increased airway resistance, this attenuates the infant's inspiratory flow and results in a slower inflation rate. The longer time constant indicates the increased time required for alveolar pressure to rise and equilibrate with the applied pressure. When airway resistance increases, the set T_i may not be long enough to achieve a desired V_T , as shown in Fig. 45.4. Although setting a longer T_i may be reasonable, this should be done cautiously because the increased airway resistance also limits the expiratory flow and prolongs the time required to achieve complete exhalation. A long T_i combined with a T_e that does not allow complete exhalation will result in gas trapping.

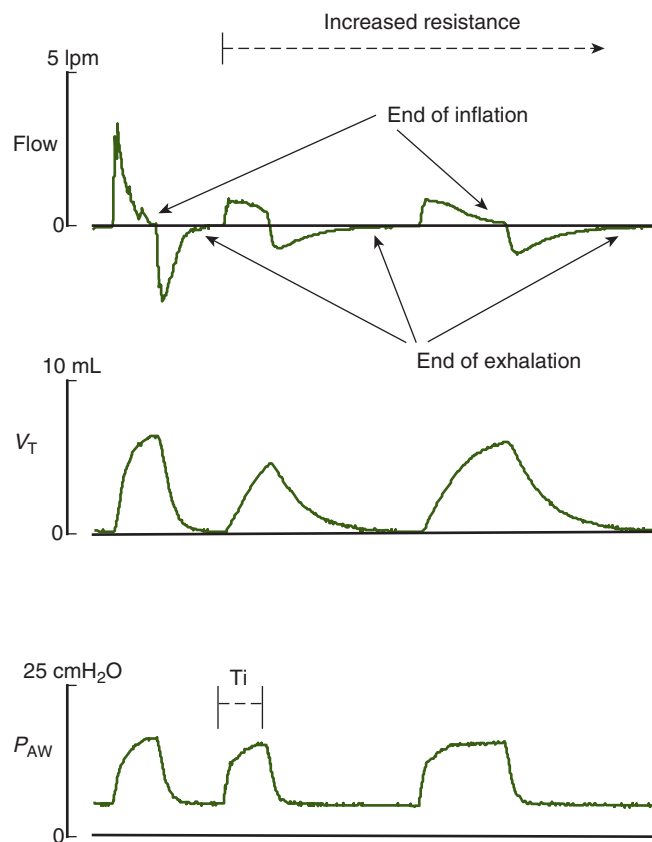

• **Fig. 45.3** Effect of Lung Compliance. Recordings of flow, tidal volume (V_T), and airway pressure (P_{AW}) showing the effects of a decrease in lung compliance. A reduction in lung compliance results in a proportional decrease in V_T for the same driving airway pressure. The effect is also noted by a shorter time constant, indicated by an earlier return of the inspiratory flow to zero, marking the end of lung inflation. *CRS*, Compliance of the respiratory system; *lpm*, liters per minute.

Modes of Conventional Positive Pressure Ventilation

The modes of conventional neonatal ventilation are generally classified according to the parameter controlled by the ventilator in each cycle as well as by the timing and duration of the cycle. Ventilator cycles can be pressure controlled or volume controlled depending on whether the ventilator targets a set peak pressure or volume respectively. Ventilator cycles can be delivered at fixed intervals regardless of the timing with respect to the infant's spontaneous breathing, or they can be delivered in synchrony with the spontaneous inspiration. The duration of the inspiratory phase of each ventilator cycle can be constant, or it can adapt to the time required to complete lung inflation, deliver the set volume, or reach the end of spontaneous inspiration.

Intermittent Mandatory Ventilation

The time-cycled pressure-limited ventilation mode described earlier and illustrated in Fig. 45.1 has been most commonly known as *intermittent mandatory ventilation* (IMV). This mode can be classified as pressure controlled because ventilator cycles deliver the PIP set

• **Fig. 45.4** Effect of Airway Resistance. Recordings of flow, tidal volume (V_T), and airway pressure (P_{AW}) showing the effects of an increase in airway resistance. The increase in resistance results in a decrease in inspiratory flow that does not permit delivery of V_T in the set inspiratory time (T_i). The prolonged time constant is noted by the increased time required to achieve full inflation and to complete exhalation. *lpm*, Liters per minute.

by the caregiver. These cycles are of constant inspiratory duration (i.e., T_i) and are delivered at fixed intervals (i.e., T_e is determined by the set ventilator frequency). For many years IMV was one of the most commonly used modes of neonatal ventilation during the acute phase as well as the more chronic phases of neonatal respiratory disease.

In IMV the increase in airway pressure in each ventilator cycle produces a given lung inflation during the set T_i . If the T_i is too short, complete lung inflation may not be achieved, whereas a long T_i that maintains a pressure plateau does not achieve a larger V_T and instead produces an inspiratory hold while the lung is kept inflated as illustrated in Fig. 45.5. In infants with respiratory failure, the T_i is usually set in the range of 0.25 to 0.4 seconds. Caution should be exercised when one is setting ventilator cycles of longer T_i or high ventilator frequencies that could result in gas trapping due to an insufficient T_e to allow full exhalation as shown in Fig. 45.6. This is particularly important when the infant's time constant is long because of a high airway resistance or when the ventilator frequency results in a T_e of less than 0.5 seconds.

During IMV, total minute ventilation results from the ventilation produced by the ventilator and the contribution of the infant's spontaneous breathing effort. During clinical use, PIP is usually adjusted to maintain the V_T between 3 and 6 mL/kg of body weight, which is considered adequate for infants with lung disease. The ventilator frequency is adjusted depending on the infant's ability to contribute to minute ventilation and maintain

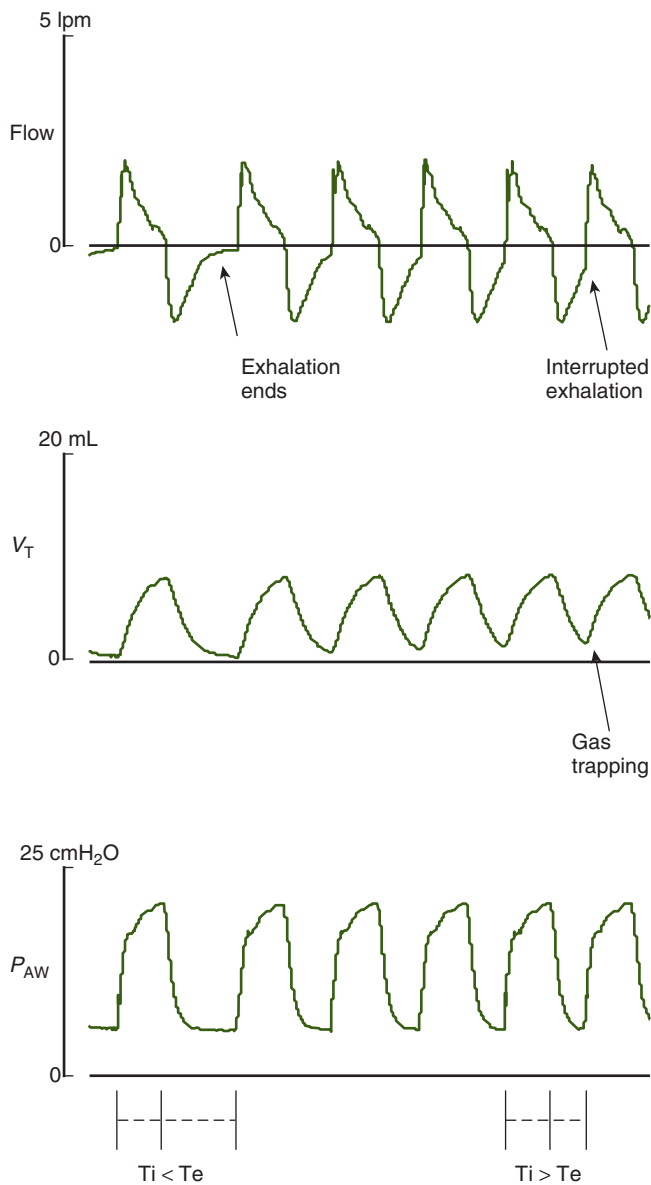

• **Fig. 45.5** Inspiratory Duration. Recordings of flow, tidal volume (V_T), and airway pressure (P_{AW}) illustrating the effects of inspiratory time (T_i). A T_i that prolongs the inspiratory phase beyond the time needed to achieve inflation does not increase the V_T and only keeps the lung expanded. A T_i of insufficient duration does not permit achievement of full inflation, as indicated by an inspiratory flow that does not return to zero and leads to a decrease in V_T . *lpm*, Liters per minute.

sufficient gas exchange. PaCO_2 levels between 40 and 50 mmHg are considered adequate in infants with acute respiratory failure, but higher levels are often accepted in infants with long-term ventilator dependency.

Although the management of IMV is relatively simple, there are some important considerations. With IMV, cycles are often delivered out of synchrony with the infant's inspiration (Greenough et al., 1983a, 1983b). Asynchronous ventilator cycles delivered toward the end of the infant's inspiration can prolong or increase lung inflation. IMV cycles delivered during the infant's exhalation can prolong its duration and in some cases elicit active exhalation against the positive pressure.

Synchronized Intermittent Mandatory Ventilation

SIMV is for the most part similar to IMV except that ventilator cycles are delivered in synchrony with the onset of spontaneous inspiration. In SIMV, ventilator management is similar to that in IMV during the different phases of respiratory failure. SIMV was rapidly accepted after its introduction in the 1980s and has become one of the most common modes of neonatal ventilation. During

• **Fig. 45.6 Gas Trapping.** Recordings of flow, tidal volume (V_T), and airway pressure (P_{AW}) illustrating the potential for gas trapping at high ventilator rates. As the ventilator rate increases, the expiratory time (T_e) becomes insufficient to complete exhalation where every exhalation is interrupted by a new ventilator cycle. This produces a volume of gas trapped in the airways and alveoli and a reduction in V_T . *lpm*, Liters per minute; *Ti*, inspiratory time.

SIMV, spontaneous breathing is continuously monitored by the ventilator, and the first spontaneous inspiration during a time window of constant duration triggers a ventilator cycle. These time windows are opened consecutively, and their duration is similar to the interval between cycles in IMV. If no spontaneous inspiration is detected by the time the window elapses, a backup ventilator cycle is delivered. In this manner the number of ventilator cycles the infant receives every minute is the same as in IMV, but the interval is not constant.

Different techniques have been incorporated into neonatal ventilators to achieve synchronization, including the Graseby abdominal pressure capsule, esophageal balloons, transthoracic impedance, airway pressure changes, phrenic electrical activity,

and flow sensors. The last are used by most neonatal ventilators for synchronization and V_T monitoring.

SIMV produces a greater and more consistent V_T in comparison with IMV because of the increased transpulmonary pressure in ventilator cycles that are in synchrony with spontaneous inspiration (Bernstein et al., 1994; Hummler et al., 1996). Thus lower PIP and slightly shorter T_i are often sufficient because the infant's inspiratory effort contributes to the generation of the V_T . As lung disease subsides, the infant's lung mechanics improve, spontaneous breathing effort becomes more consistent, and PIP is gradually adjusted to maintain a V_T between 3 and 6 mL/kg. During acute respiratory failure, a ventilator SIMV frequency ranging between 40 and 60 breaths per minute is usually required to maintain P_{aCO_2} between 40 and 50 mmHg. At this frequency, SIMV is likely to assist almost all spontaneous breaths. During weaning, the SIMV frequency is gradually reduced as spontaneous unassisted breathing can better maintain acceptable P_{aCO_2} levels. In infants with chronic lung disease, higher P_{aCO_2} levels are often tolerated for reduction of the ventilator settings as long as respiratory acidosis is not observed. The relative advantages of SIMV in comparison with IMV include faster weaning and a shorter ventilator dependency, with improved respiratory outcome in the smaller infants (Bernstein et al., 1996; Chen et al., 1997).

As the SIMV frequency is reduced, the spontaneous breathing effort must be able to sustain most of the ventilation, thus requiring a greater breathing effort. It has been suggested that the work of breathing in unassisted spontaneous breaths between SIMV cycles is counterproductive and can potentially lead to diaphragmatic fatigue. Conversely, it has also been suggested that exposure to fewer ventilator cycles may reduce the risk of lung injury and improve diaphragmatic fitness toward an eventual extubation. Failure to trigger breaths leads the ventilator to cycle at the backup IMV rate. Delayed cycling prolongs the duration of inspiration and can disrupt the breathing pattern (Beck et al., 2004), whereas autocycling produces asynchrony between the ventilator and the infant.

Assist/Control Ventilation

In A/C ventilation, every spontaneous inspiration is assisted by a synchronous ventilator cycle. If the ventilator does not detect spontaneous breaths because of either apnea or very shallow breathing, it provides an IMV rate with the same PIP as the assisted breaths. A/C ventilation can also be used during the acute and weaning phases of respiratory failure.

A/C ventilation is primarily managed by adjustment of PIP to maintain the V_T within an adequate range. As the respiratory failure resolves with improving lung mechanics and stronger spontaneous breathing effort, PIP is gradually reduced as long as the V_T remains within an acceptable range. In the more immature infants, the respiratory drive is not consistent, and such infants have frequent apnea. Thus the "controlled" or backup IMV rate becomes more relevant in the maintenance of ventilation during apnea.

In infants with respiratory failure, the T_i required to achieve lung inflation usually ranges between 0.25 and 0.4 seconds. A longer T_i is not recommended because of the potential for gas trapping with ventilator cycles delivered at the infant's often high breathing frequency. A long T_i can also disrupt spontaneous breathing (Upton et al., 1990; Dimitriou et al., 1998; Beck et al., 2004). Most modern ventilators provide flow cycling where the T_i terminates at the end of the spontaneous inspiration or at the end of lung inflation. The advantages of A/C ventilation include

a reduction in spontaneous breathing effort relative to IMV or SIMV because in contrast to these modes, A/C ventilation assists every inspiration (Bernstein et al., 1994; Kapasi et al., 2001). It has been suggested that assisting every spontaneous inspiration in A/C mode ventilation prevents diaphragmatic fatigue and can reduce the duration of weaning and ventilator dependency compared with IMV (Baumer, 2000; Beresford et al., 2000; Chan and Greenough, 1993; Donn et al., 1994). However, A/C ventilation has not been shown to be more effective than SIMV (Chan and Greenough, 1994; Dimitriou et al., 1995).

In A/C ventilation, PIP should be adjusted to avoid a large V_T that can produce hyperventilation, whereas the backup rate should be just sufficient to prevent hypoventilation during apnea. Auto-cycling is a problem in A/C mode ventilation because neonatal ventilators do not have a limit on the cycling frequency and therefore can produce hyperventilation and gas trapping.

Pressure Support Ventilation

Similarly to A/C mode ventilation, in pressure support ventilation (PSV) the ventilator provides a positive pressure breath with every spontaneous inspiratory effort. The start of the support pressure is in synchrony with the onset of the spontaneous inspiration, and termination of the support pressure occurs toward the end of spontaneous inspiration or when lung inflation is completed (i.e., flow cycling). The use of PSV is aimed at unloading the respiratory pump with support pressure that helps overcome the elastic and resistive loads imposed by the preterm infant's underlying lung disease. PSV can be used as a stand-alone mode with an IMV backup rate for apnea or in some ventilators as an adjunct to SIMV to assist the spontaneous breaths, whereas the SIMV cycles with a higher peak pressure are used to maintain lung volume.

Although PSV can be used during both the acute phase and the weaning phase of respiratory failure, it is most commonly used during weaning. A consistent respiratory drive is required for the use of PSV as a stand-alone mode. For this reason, a backup IMV rate is recommended particularly in preterm infants to prevent hypoventilation. During PSV, gas leaks around the ETT can produce autocycling and extend the duration of the cycle. To avoid the risk of hyperventilation or gas trapping, the trigger and termination sensitivity levels must be adjusted, and limits on the cycle duration must be set.

When PSV is used as an adjunct to SIMV, it can reduce the spontaneous breathing effort compared with SIMV alone even with support pressures set at a fraction of the peak pressures of the SIMV cycles (Osorio et al., 2005; Gupta et al., 2009; Patel et al., 2009). More importantly, by reducing the need for high SIMV rates, PSV can facilitate weaning in comparison with SIMV alone (Reyes et al., 2006). In that study, PSV levels set at 30% to 50% of the peak pressure of the SIMV cycles were sufficient to maintain acceptable PaCO_2 levels with significantly lower SIMV rates, and infants supported with SIMV plus PSV were weaned faster off respiratory support and supplemental oxygen.

Volume-Targeted Ventilation

In volume-targeted ventilation, automatic adjustments to the peak positive pressure or the duration of the ventilator cycle are done to maintain a target V_T . Volume-targeted ventilation modes have been proposed as a means to reduce ventilator-associated lung injury caused by ventilation with excessive or insufficient V_T s during conventional pressure-controlled ventilation. A number of volume-targeted modes are available in neonatal ventilators. These differ in the timing of the adjustment or in the duration of the mechanical

cycle (i.e., whether it occurs as the cycle is delivered to the infant or in the subsequent cycle). These modes also differ in the volume parameter that is controlled—whether it is the V_T received by the infant or the volume delivered by the ventilator to the circuit and whether this is measured during the inspiratory phase or during exhalation.

Metaanalyses comparing different volume-targeted ventilation strategies with pressure-limited ventilation showed decreased duration of ventilation and decreased incidence of BPD, pneumothorax, severe intraventricular hemorrhage (IVH), and periventricular leukomalacia with use of volume-targeted ventilation (Wheeler et al., 2011; Peng et al., 2014).

Volume-Controlled Ventilation. In volume-controlled (VC) ventilation the ventilator delivers a set volume of gas into the ventilator circuit in each cycle. VC ventilation cycles are delivered in the IMV, SIMV, or A/C ventilation modes described earlier. The time required to deliver the set volume depends on the ventilator flow rate, which can be constant during the cycle or variable, with an initial peak followed by a gradual decline. The flow continues until the set volume is delivered. The cycle ends before the set volume is delivered if its duration exceeds the set T_i or the airway pressure exceeds the set PIP. In small infants, most of the volume delivered by the ventilator is compressed in the circuit, and the actual V_T delivered to the infant is only a fraction. Some ventilators use algorithms to correct the measured volume by the compressed volume to estimate the true V_T .

VC ventilation has been proposed as a strategy to facilitate weaning and reduce the complications of positive pressure ventilation. Clinical trials showed that compared with pressure-limited ventilation in the A/C mode, VC ventilation reduced the weaning time and the duration of mechanical ventilation in infants weighing at least 1200 g at birth (Sinha et al., 1997). Weaning was also faster with VC ventilation in infants of birth weight less than 1000 g, but the total duration of mechanical ventilation did not change, and respiratory outcome did not differ significantly (Singh et al., 2006).

Pressure-Regulated Volume-Controlled Ventilation. In pressure-regulated VC (PRVC) ventilation, the peak pressure of pressure-controlled ventilator cycles is adjusted from one cycle to the next to maintain a target volume. The targeted volume can be that delivered by the ventilator or the actual estimated or measured V_T . During PRVC ventilation, gas leaks around the ETT can produce overestimation of volume during the inspiratory phase and consequently lead to inappropriate reductions in PIP.

Compared with conventional IMV, PRVC ventilation in A/C mode was effective in reducing the duration of mechanical ventilation and the incidence of IVH in infants with RDS of birth weight less than 1000 g (Piotrowski et al., 1997). These advantages can be attributed, in addition to volume targeting, to synchronized delivery PRVC ventilation cycles. These advantages were not evident when PRVC ventilation was compared with SIMV (D'Angio et al., 2005).

Volume Guarantee Ventilation. Volume guarantee (VG) ventilation is one of the more commonly used volume-targeted modes of ventilation in neonates. In VG ventilation, the peak pressure of each ventilator cycle is adjusted to maintain a target V_T based on the basis of exhaled V_T measured in previous cycles. Measurement of exhaled V_T is aimed at circumventing the effects of gas leaks around the ETT during the inspiratory phase. VG ventilation can be used in combination with the A/C, PSV, SIMV or IMV modes of ventilation. Practical details on how to use VG ventilation are discussed in Klingenberg et al. (2011).

VG ventilation was proposed as a potential alternative to avoid both extremes of V_T and to achieve a consistent reduction of peak pressure. The stability of V_T and gas exchange in infants with RDS can be enhanced by VG ventilation when combined with A/C mode ventilation or PSV as noted by fewer breaths with too small or large V_T and less hypocapnia (Abubakar and Keszler, 2001; Herrera et al., 2002; Keszler and Abubakar, 2004; Cheema et al., 2007). In infants with RDS or who had received surfactant, VG ventilation achieved the proper reduction in PIP, but this was dependent on the setting of a lower target V_T than the V_T attained with the pressure-controlled modes (Abubakar and Keszler, 2001; Cheema and Ahluwalia, 2001; Herrera et al., 2002; Olsen et al., 2002; Abd El-Moneim et al., 2005; Nafday et al., 2005). However, the smaller target V_T was in some cases not sufficient, resulting in increased PCO_2 and spontaneous breathing effort (Herrera et al., 2002). Although there is some evidence that use of VG ventilation may improve short-term respiratory outcomes, such as the duration of mechanical ventilation, its effect on long-term outcomes, such as BPD and NDI, has not been fully evaluated (Duman et al., 2012; Stefanescu et al., 2015).

VG ventilation has also been proposed as a means to attenuate hypoxemia spells triggered by hypoventilation during periods of agitation and decreased compliance in preterm infants. Studies evaluating the use of VG ventilation to reduce hypoxemia have shown mixed results. While use of VG ventilation in controlled settings with target V_T higher than that during SIMV reduced the duration of the hypoxemia spells (Polimeni et al., 2006), the effect was less marked in a study where the target V_T during VG ventilation was matched to that during SIMV (Jain et al., 2016).

Proportional Assist Ventilation

In proportional assist ventilation (PAV) the ventilator pressure is increased in proportion to the measured volume or flow, or both, generated by the infant's inspiratory effort. This achieves a perceived reduction of the elastic and resistive loads imposed by lung disease that commonly prevent the infant from producing an adequate V_T . The proportionality factors by which the positive pressure increases in relation to volume or flow are the elastic (volume proportional) and resistive (flow proportional) gains. The elastic and resistive gain factors must be individualized to each infant's lung compliance and airway resistance and the infant's ability to cope with the loads. Elastic gain factors that exceed the lung elastance (inverse of compliance) can lead to a runaway increase in pressure, whereas excessive resistive gain factors can produce oscillations in airway pressure. For this reason, PAV devices provide peak pressure and volume limits. Because PAV amplifies only the spontaneous breathing effort, a backup IMV rate is needed to prevent hypoventilation during apnea.

By compensating for the loads induced by lung disease, PAV reduced the breathing effort in infants recovering from RDS (Musante et al., 2001). Compared with conventional modes that deliver a constant pressure during inspiration, PAV produced similar ventilation with lower ventilator and transpulmonary pressures (Schulze et al., 1999, 2007) as well as improved oxygenation (Bhat et al., 2015; Shetty et al., 2016).

Neurally Adjusted Ventilatory Assist

NAVA is a mode where the ventilator pressure is adjusted in proportion to the electrical activity of the diaphragm measured by esophageal electrodes. NAVA was developed to enhance the coupling of the infant's inspiration and the ventilator response.

Short-term studies in premature infants showed that NAVA can increase synchrony between the infant's spontaneous breaths and the ventilator and that it can maintain similar or better ventilation and gas exchange with less breathing effort and lower ventilator pressures compared with conventional pressure-controlled ventilation (Beck et al., 2009; Lee et al., 2012; Stein et al., 2013; Longhini, 2015). Of note, these effects are relative to the NAVA gain level used as well as the settings during conventional ventilation. Further studies are needed to determine the impact of NAVA in the preterm infant population.

Management of the ventilatory support during NAVA differs substantially from that with conventional modalities. In NAVA the support level is adjusted by the setting of the NAVA gain (Stein et al., 2014). However, data are lacking on the effects of different NAVA proportionality factors between diaphragmatic electrical activity and ventilator pressure within the same infant or between infants, because electrical activity of the diaphragm cannot be normalized. The respiratory drive in premature infants is inconsistent, and they frequently have apneic episodes. For this reason a backup mechanical support is needed to prevent hypoventilation during these episodes.

Targeted Minute Ventilation

Targeted minute ventilation (TMV) is a mode where the ventilator rate is adjusted to maintain minute ventilation at a target level. If minute ventilation exceeds or decreases below the target level, the ventilator rate is reduced or increased respectively. If spontaneous breathing can maintain a normal minute ventilation, the ventilator rate is reduced. In preterm infants recovering from RDS, TMV reduced the ventilator rate to half the original rate without impairing gas exchange compared with SIMV. Although these infants were able to sustain their ventilation for long periods, at times they required increased ventilator rates (Claure et al., 1997).

Mandatory minute ventilation (MMV) is a form of TMV where the ventilator rate is transiently turned to zero when spontaneous breathing maintains ventilation. If minute ventilation falls below the target level, a constant ventilator rate of VC ventilation cycles is provided. In near-term infants ventilated for reasons other than lung disease, MMV reduced the rate and reduced the mean airway pressure compared with SIMV (Guthrie et al., 2005).

Adaptive backup ventilation is a form of backup support. In this mode a ventilator rate is provided during apnea as well as during hypoxemia detected by SpO_2 . In preterm infants recovering from RDS, this hybrid backup mode compared with a backup ventilator rate for apnea alone reduced the incidence and duration of hypoxemia spells (Herber-Jonat et al., 2006).

High-Frequency Ventilation

Because of the association between pulmonary overdistension, lung injury, and the development of BPD, the possibility of achieving gas exchange with very small V_T s has been of great interest to neonatologists for many years. This led to the development of instruments that can generate changes in airway pressure at rates in excess of 10 Hz (600 per minute) with the aim of producing ventilation with very small V_T s, usually much smaller than the dead space.

Gas Transport During High-Frequency Ventilation

During conventional ventilation, gas exchange occurs by introduction of fresh gas into the distal air spaces with each inspiration. In contrast, during HFV, the volume of fresh gas delivered by each

cycle is very small and does not reach the most distal portions of the lung. Therefore different mechanisms must explain alveolar ventilation and gas exchange. These include bulk flow into the more proximal portions of the lung, enhanced mixing of gas within the conducting airways, and out-of-phase movement between different regions of the lung that have different time constants. There is also enhanced diffusion of gas in large and medium-sized airways due to asymmetric velocity profiles during inspiration and expiration. Finally, there is molecular diffusion in the more distal air spaces that moves the different gas molecules from areas of higher concentration to areas of lower concentration. These mechanisms have been mostly explored in adult lung models, and therefore it is not clear how well they apply to the immature or sick neonatal lung.

Devices for High-Frequency Ventilation

Several types of high-frequency ventilators have been used in the neonate, including jet ventilators, oscillators, and flow interrupters.

Jet ventilators generate a high-velocity gas flow that is injected through a small-diameter tube that opens into the airway connector. Expiration is passive, and the cycling rate is determined by an electrically operated valve that opens and closes the jet at a pre-determined rate and timing. The high velocity of the gas injected into the airway produces a Venturi effect that pulls additional gas from the ventilator circuit. This is known as *gas entrainment*. V_T is determined primarily by the driving pressure of the gas, the T_i , and the resistance of the injection port. Because expiration is passive during high-frequency jet ventilation (HFJV), there is a risk of gas trapping and lung overdistension (Bancalari et al., 1987). This risk is higher when the time constant of the respiratory system is increased by airway obstruction and when large V_T s are delivered. Because of this, jet ventilators are used at lower rates (4 to 10 Hz). Jet ventilators are used in combination with conventional ventilators that provide PEEP and may also provide conventional positive pressure cycles.

High-frequency oscillatory ventilators use a piston or a membrane driven by an electromagnetic force and connected to the ventilator circuit. The mean airway pressure is determined by the gas flow through the circuit and a variable resistance, whereas the V_T is generated by the size of the excursion of the piston or membrane. With these devices, the expiratory phase is active because during expiration, airway pressure falls below the baseline, which reduces the risk of gas trapping.

Flow interrupters are a hybrid between jet and oscillatory ventilators. They produce airway pressure changes by interrupting the gas flow at very high rates using a standard ventilator circuit rather than an injection cannula. They are relatively simple and are usually offered as an additional mode on some conventional neonatal ventilators. They are often used on transport ventilators. However, they may not have enough power to generate sufficient pressure amplitude to effectively ventilate large infants or infants with very stiff lungs.

Ventilator Settings During High-Frequency Ventilation

The ventilator settings during HFV are simpler to adjust than with conventional ventilation. The mean airway pressure determines the lung volume and is adjusted to optimize the ventilation-perfusion ratio and oxygenation. This is done considering the severity and type of lung disease. Most infants with RDS are managed with mean airway pressures between 8 and 15 cmH₂O. Higher levels may be necessary in some cases with severe lung disease and poorly compliant lungs.

The V_T is determined by the pressure amplitude, and this, in combination with the frequency, determines the CO₂ elimination. In contrast to conventional ventilation, during HFV the V_T is reduced as the frequency increases because the shorter times for inspiration and expiration prevent the equilibration of pressures between the ventilator circuit and the distal portions of the lung. Therefore during HFV a reduction in rate may result in larger V_T s, more CO₂ elimination, and lower PaCO₂ levels.

During high-frequency oscillation or with flow interrupters, the frequencies used range from 8 to 15 Hz, whereas during jet ventilation lower frequencies between 4 and 10 Hz are commonly used.

The pressure transmission to the distal airways is greatly influenced by the resistance of the tube and the airway, so only a small fraction of the delta pressure generated by the ventilator is transmitted to the terminal air spaces. For this reason, the delta pressure during HFV represents more a relative value used to adjust the ventilator than the real pressure change in the distal airways.

Clinical Use of High-Frequency Ventilation

The indications for HFV differ widely among different centers. Although some use HFV routinely as a primary mode of support, most centers use it as rescue when conventional ventilation has failed. This includes use in preterm infants who require increasing ventilator settings to maintain CO₂ elimination and oxygenation within acceptable limits and those with evidence of pulmonary interstitial emphysema. In larger infants, HFV is also indicated in situations where conventional ventilation is not sufficient to maintain acceptable CO₂ elimination or oxygenation and especially in infants with persistent pulmonary hypertension secondary to hypoplastic lungs due to congenital diaphragmatic hernia or oligohydramnios or to severe lung disease due to meconium aspiration or pneumonia.

High-Frequency Ventilation in Respiratory Distress Syndrome

The clinical results with the use of HFV in infants with RDS have been inconsistent. Whereas some studies have shown better outcomes, such as increased survival with no BPD (Courtney et al., 2002; Sun et al., 2014), others have not shown differences (Johnson et al., 2002). Some studies have suggested a higher risk of air leaks (Thome et al., 1999), and others have suggested a higher incidence of intracranial hemorrhage with HFV (HIFI Study Group, 1989; Moriette et al., 2001).

Many of the earlier studies were performed before exogenous surfactant was available, and therefore the results are not entirely applicable to the present situation, where most preterm infants are exposed prenatally to steroids and, when indicated, receive exogenous surfactant. A metaanalysis of the most recent trials suggests a possible advantage for HFV in the outcomes “BPD at 36 weeks” or “death or BPD” at 36 weeks’ corrected age. However, when the results were analyzed with use of adjustments for heterogeneity between trials, the beneficial effect disappeared (Thome et al., 2005). The results of this metaanalysis revealed a significant increase in the risk of air leaks and a trend for higher risk of IVH grades III and IV with HFV. When the results of HFV were compared with those of conventional ventilation, including only studies where HFV was used with high-volume strategies and conventional ventilation was used with an optimized low positive pressure and V_T strategy, there were no significant differences in any of the outcomes (Thome et al., 2005; Bollen et al., 2007). Because of the inconsistency of the results and the lack of solid evidence for benefits of HFV over conventional ventilation in

infants with RDS, the selection of one modality over the other is mostly based on individual preference (Cools et al., 2015). This is also true for the use of HFJV because of the limited evidence of a positive impact on mortality, BPD, or other neonatal morbidities (Rojas-Reyes et al., 2015).

High-Frequency Ventilation in Persistent Pulmonary Hypertension of the Newborn

The clinical evidence with the use of HFV in infants with persistent pulmonary hypertension is not solid and comes from a few, relatively small trials. Some of these studies suggested a decreased need for extracorporeal membrane oxygenation in infants with persistent pulmonary hypertension treated with HFV compared with those treated with IPPV (Clark et al., 1994). However, other studies have not shown a clear advantage of HFV over conventional ventilation (Kinsella et al., 1997; Rojas et al., 2005). HFV may offer some advantage over conventional ventilation in infants with hypoplastic lungs secondary to congenital diaphragmatic hernia or other prenatal conditions (Desfrere et al., 2000).

Other Indications for High-Frequency Ventilation

HFV has also been used in infants with bronchopleural fistulas in an attempt to reduce the amount of gas leak into the pleural space (Gonzalez et al., 1987; Walsh and Carlo, 1989). It can also be used during bronchoscopy or during airway surgery because in contrast to conventional ventilation, it can produce adequate gas exchange with a partially open airway and large gas leaks (Nutman et al., 1989).

Side Effects of High-Frequency Ventilation

Because during HFV the V_T s are extremely small, when HFV is used in unstable lungs, there is a possibility of progressive loss of lung volume and atelectasis. For this reason it is necessary to use mean airway pressures that are usually higher than those used during conventional IPPV to maintain lung recruitment. There is evidence that during HFV the use of an open lung strategy using recruiting maneuvers and high mean airway pressures produces better outcomes than use of lower pressures (Thome et al., 2005). As a result of these higher pressures, it is possible that HFV may negatively influence cardiovascular function (Trindade et al., 1985; Truog and Standaert, 1985; Weiner et al., 1987; Osborn and Evans, 2003), and this may explain the higher incidence of pneumothorax reported in some studies with HFV (Thome et al., 2005).

Because of the effectiveness of HFV in enhancing alveolar ventilation, it is easy to drive PaCO_2 to very low values within a very short period. For this reason it is important to monitor PaCO_2 values closely, especially when HFV is initiated or when settings are changed. Because of the very short inspiratory and expiratory times, it is extremely important to maintain the airway as patent as possible, ensuring a correct position of the ETT. Any obstruction will produce a decrease in pressure transmission and in V_T and can lead to gas trapping. This is even more important with jet ventilation because it can deliver larger V_T s. During jet ventilation, it is also critical to ensure proper humidification of the inspired gas to prevent airway damage that can be produced by the high velocity of gas injected into the airway.

Weaning of Infants off Mechanical Ventilation

Weaning of infants off IPPV may be difficult in very immature infants who have poor and inconsistent respiratory drive, a weak respiratory pump, and immature and frequently damaged lungs.

This combination of factors explains why they frequently become ventilator dependent for long periods.

For many years, infants who were ventilated received most of their minute ventilation from the ventilator and were not allowed to have effective spontaneous ventilation. In recent years this has changed, and ventilators are used as an assist support, preserving the patient's respiratory drive and effort. This has been possible by the introduction of synchronized patient-triggered ventilation (PTV) and has resulted in better outcomes and shorter times for mechanical ventilation.

Because of the high rate of complications associated with prolonged mechanical ventilation, weaning should start as soon as mechanical ventilation is started and respiratory function is stabilized. The order in which the different ventilator parameters are decreased is determined by the relative risk of complications associated with each of them. With the possibility of measuring V_T , it has become much simpler to define the appropriate PIP that is required to generate an adequate V_T of 4 to 6 mL/kg body weight. As lung compliance increases, PIP can be reduced to keep the V_T within this range.

PEEP is usually kept between 4 and 8 cmH₂O depending on the type of underlying lung disease and the level of oxygenation and FiO_2 requirement. PEEP is decreased gradually as the oxygenation increases until a level of 4 to 5 cmH₂O is reached, and this level is maintained until extubation. The inspired oxygen concentration is adjusted according to the level of arterial oxygen tension or O_2 saturation measured by pulse oximetry. The ideal ranges of oxygenation have not been defined, but most clinicians accept saturations between 88% and 95% in preterm infants and up to 98% in term infants. In infants with evidence of pulmonary hypertension, higher levels are targeted to prevent pulmonary vasoconstriction.

If V_T measurement is not available, the reduction in PIP is based on the observation of chest movement, the degree of aeration on chest radiograph, and PaCO_2 levels. The ventilator rate is adjusted depending on the type of ventilation strategy being used. When the infant is ventilated with synchronized modes such as A/C mode or pressure support mode, the infant determines the rate of the mechanical breaths, so the set rate is only the backup that the ventilator will provide when the infant's own rate falls below that level. Therefore, this rate is relevant only when the infant becomes apneic or hypoventilates. When the infant is controlled, the rate in the ventilator is not determined by the infant, and the adjustment of the mechanical rate is based on the PaCO_2 level.

During weaning, it is advisable to make gradual changes and adjust one parameter at a time to evaluate the response of the infant to each change. With the availability of continuous oxygen and CO_2 monitoring, it is not always necessary to wait for the results of arterial gas measurement to change the ventilator settings, and the weaning can proceed faster.

Synchronized Patient-Triggered Ventilation for Weaning

The use of patient-triggered synchronized ventilation has become common practice in neonatal units. Most randomized trials comparing PTV with nonsynchronized ventilation have shown a reduction in the duration of mechanical ventilation in infants treated with synchronized modes (Greenough, 2001). This may be because during PTV, the infant retains more control of ventilation, and the effectiveness of the mechanical and spontaneous breaths is enhanced by the summation of the ventilator positive pressure and the negative pressure generated by the respiratory muscles.

A/C and SIMV are the most common modes of synchronized ventilation in the neonate. It has been suggested that assisting each spontaneous inspiration in A/C mode ventilation may avoid respiratory muscle fatigue and facilitate weaning. However, the duration of weaning has not been consistently shorter with A/C mode ventilation than with SIMV (Chan and Greenough, 1994; Beresford et al., 2000). On the other hand, a randomized trial comparing the use of PSV as an adjunct to SIMV to assist every spontaneous inspiration revealed a faster weaning and shorter duration of ventilation compared with SIMV alone in preterm infants (Reyes et al., 2006).

Volume Monitoring and Volume-Targeted Ventilation During Weaning

The continuous monitoring of V_T allows rapid reduction of PIP as the mechanical conditions of the lung improve. This can be achieved by a manual decrease of PIP as the V_T increases or automatically by use of volume-targeted ventilation where weaning is achieved automatically independent of the clinician, who only sets the V_T targeted by the ventilator. Evidence from randomized trials using volume-targeting strategies suggests that faster weaning off mechanical ventilation can be achieved, although the results have not been entirely consistent (Sinha et al., 1997; Singh et al., 2006).

Weaning of Infants off High-Frequency Ventilation

Infants ventilated with HFV are frequently switched to conventional ventilation before extubation. However, infants can be extubated directly from HFV following similar steps to those used to wean infants off conventional ventilation. The reduction in mean airway pressure is done following lung expansion by use of chest radiographs, while FIO_2 is adjusted to maintain the desired oxygenation levels.

The pressure amplitude is gradually reduced in response to the levels of PaCO_2 . If the mean airway pressure is reduced to low levels before the infant has spontaneous respiratory effort, this can lead to hypoventilation, loss of lung volume, and atelectasis. For this reason, it is advisable to lower the delta pressure and allow the PaCO_2 to rise and stimulate spontaneous respiration before the mean airway pressure is lowered below 8 or 10 cmH_2O .

Permissive Hypercapnia

Tolerance of higher carbon dioxide levels may reduce the need for support and reduce the duration of ventilation. However, the results of clinical trials have been inconsistent. Whereas initial trials suggested faster weaning of infants off mechanical ventilation in the group with higher CO_2 levels (Mariani et al., 1999; Carlo et al., 2002), more recent studies showed no benefit with regard to the duration of ventilation or BPD and a trend toward an increase in mortality and central nervous system impairment in infants with higher PaCO_2 (Thome et al., 2006, 2015). These results shed doubt on the benefits of maintaining high CO_2 levels in premature infants during the acute stages of their clinical course and also demonstrate that safe ranges of CO_2 levels have yet to be determined. However, in infants with chronic lung disease, it may be necessary to tolerate high CO_2 levels so as to wean them off mechanical ventilation.

Dead Space Reduction

The large anatomic dead space in preterm infants in addition to the instrumental dead space can also delay their weaning off mechanical ventilation (Figueras et al., 1997).

Continuous tracheal gas insufflations through small capillaries to the distal end of the ETT to produce a continuous washout can reduce arterial CO_2 and shorten the weaning process (Dassieu et al., 2000). This method is limited by the need for special ventilators and an ETT. Continuous washout of the flow sensor by a controlled gas leak can also increase CO_2 elimination and facilitate weaning (Claire et al., 2003; Estay et al., 2010).

Automated and Computer-Assisted Weaning

In the TMV mode described earlier, the ventilator rate is automatically reduced during periods of consistent spontaneous breathing where minute ventilation is maintained at or above the target level. In a study of preterm infants recovering from RDS, this experimental mode reduced the ventilator SIMV rate set by the clinical team by half while SpO_2 and TcPCO_2 remained unchanged (Claire et al., 1997). A similar reduction in rate was observed in near-term infants without lung disease when supported by MMV, a mode where the ventilator rate is transiently turned to zero when spontaneous minute ventilation exceeds a set level or delivers a set rate of volume-controlled breaths when minute ventilation decreases below this level (Guthrie et al., 2005).

Preterm infants often need supplemental O_2 , which increases their risk of eye and lung injury, particularly when exposure to oxygen is prolonged. In these infants, hyperoxemia is induced by an excessive FIO_2 , and therefore it is modifiable by appropriate weaning. Automated weaning of infants off supplemental oxygen was achieved by systems developed to adjust FIO_2 in a continuous manner. Systems of automated FIO_2 control have been shown to be as effective as or more effective than routine or dedicated manual control in maintaining oxygenation within a desired range, with most of the improvement due to significant reductions in hyperoxemia (Claire et al., 2009, 2011).

Ventilator management involves adjustments of several parameters that affect the infant's ventilation and gas exchange. Computerized algorithms for ventilator management have been proposed to achieve efficient and consistent weaning. In infants with RDS, ventilator management assisted by one of these algorithms led to improvements in gas exchange and avoided unnecessary increases in ventilator settings (Carlo et al., 1986). During routine care, hypoxemia and hypercapnia were more diligently corrected than hyperoxia and hypocapnia, whereas computer-assisted management was similarly effective in correcting both extremes. The potential beneficial effects of computer-assisted weaning on long-term outcome have not been explored.

Extubation

It is difficult to decide the best time for extubation in ventilated infants. It is obvious that many infants remain intubated for longer than necessary. This is evidenced by the fact that many infants who are accidentally extubated tolerate it well without needing further respiratory support. Various tools have been evaluated to predict successful extubation. These include measurement of lung mechanics, minute ventilation, inspiratory effort strength and ability to cope with mechanical loads, and stability of the respiratory pattern during periods when the ventilator cycling is stopped (Kamlin et al., 2006). Some of the tools have been shown to predict with some accuracy successful extubation, but these tests have not been widely accepted in neonatal clinical practice.

The decision to extubate an infant is usually based on the level of inspired oxygen and ventilator support that the infant is requiring to maintain acceptable arterial blood gas levels. In general terms, if an

infant needs less than 30% to 40% oxygen, a ventilator rate less than 15 per minute, and a PIP below 15 cmH₂O and maintains acceptable blood gas levels, most clinicians attempt extubation. The lower the gestational age, the more likely it is that the infant will not tolerate extubation and will require reintubation. In most cases this failure is because of poor respiratory effort or severe apneic episodes.

Nasal Continuous Positive Airway Pressure and Noninvasive Ventilation for Extubation

After extubation, the infant is exposed to a number of mechanical impediments that explain the frequent need for reintubation in the smaller preterm infants. These include upper airway damage and retained secretions leading to obstruction and atelectasis, loss of lung volume due to poor respiratory effort, and a highly compliant chest wall. For these reasons the use of CPAP applied through the nose can significantly reduce the deterioration that occurs frequently after extubation. Surprisingly, despite this improvement in respiratory function, the need for reintubation has not been consistently shown to be reduced by the use of N-CPAP after extubation (Davis and Henderson-Smart, 2003).

In contrast with the use of N-CPAP, the use of nasal ventilation after extubation has been shown to significantly reduce extubation failure (Davis et al., 2001; De Paoli et al., 2003). Although these studies have included small numbers of infants, the effects have been consistent. This is a promising therapeutic alternative that needs further evaluation and the development of suitable equipment to provide synchronized noninvasive support.

Use of an HFNC for respiratory support after extubation has been explored recently in randomized controlled trials, with most of the trials showing trends toward higher rates of extubation failure with use of an HFNC compared with use of CPAP (Manley, 2013; Yoder, 2013). It is important to note that many of these trials enrolled infants of higher gestational age and with lower risk of extubation failure. It is likely that infants with significant lung disease at the time of extubation will also benefit from use of CPAP or nasal ventilation.

Respiratory Stimulants for Extubation

Respiratory stimulants such as aminophylline and caffeine have been shown to be effective in increasing respiratory center activity in preterm infants and in decreasing the incidence of severe apneic episodes. These drugs have also been shown to facilitate successful weaning of infants off mechanical ventilation and to decrease the need for reintubation. For this reason most preterm infants receive a loading dose of caffeine or aminophylline before extubation, and they are maintained with these stimulants at least during the first few days after extubation while they are also maintained with CPAP therapy or nasal ventilation (Henderson-Smart and Davis, 2003).

Acute Complications of Respiratory Support

Pulmonary Gas Leaks

One of the most serious complications of mechanical ventilation is pulmonary gas leaks. These include pulmonary interstitial emphysema, pneumothorax, pneumomediastinum, pneumopericardium, pneumoperitoneum, and intravascular gas.

Pulmonary Interstitial Emphysema

PIE is the result of rupture of air spaces from overdistension. Although it may be seen in infants breathing spontaneously, it is more common in preterm infants undergoing mechanical ventilation

• **Fig. 45.7** Pulmonary Interstitial Emphysema. A grossly hyperinflated lung with coarse radiolucencies extending from the pleura to the hilum. These radiolucencies represent gas bubbles in the perivascular and peribronchial interstitial cuffs.

and in infants with evidence of pulmonary infection. Once alveolar rupture occurs, gas is forced from the air spaces into the connective tissue sheaths surrounding airways and vessels and into the interlobular septa containing pulmonary veins. The air follows a track along these sheaths to the hilum of the lung, producing the characteristic radiographic appearance of PIE (Fig. 45.7). The PIE occupies space within the lung parenchyma, decreasing lung compliance. Gas trapped within the interstitial cuffs compresses airways and increases airway resistance. In addition, gas in the interstitial space impairs lymphatic drainage, increasing the amount of interstitial fluid. This can lead to a significant deterioration in gas exchange, with an increase in PaCO₂ and a decrease in PaO₂.

The main cause of PIE is air space overdistension and rupture. Therefore minimization of pulmonary overdistension should reduce the risk of PIE. Shorter T_{is} also decrease the incidence of PIE by reducing overdistension and avoiding an inspiratory hold (Heicher et al., 1981; OCTAVE Study Group, 1991).

PIE is a serious complication of mechanical ventilation. Infants with PIE have a significantly increased risk of developing chronic lung disease as well as higher mortality rates (Gaylord et al., 1985; Powers and Clemens, 1993).

Because the gas leak can behave like a check valve, gas trapping occurs, resulting in further alveolar overdistension and rupture. Therefore the first step in treatment must be to interrupt this cycle by putting to rest the more severely involved areas in the lung. If PIE is unilateral, this can be accomplished by the positioning of the infant with the involved side down (Swingle et al., 1984). Mechanical ventilation using short T_{is} (0.1 to 0.2 seconds), low inflation pressures, and small V_Ts can reduce the gas leak (Meadow and Cheromcha, 1985). Unfortunately, it is difficult to maintain oxygenation and ventilation while low volumes are being used. A multicenter controlled trial found that HFJV allowed the use of lower peak and mean airway pressures in infants with PIE than did rapid-rate conventional ventilation and led to more rapid relief of PIE (Keszler et al., 1991).

Pneumothorax

Pneumothorax can occur spontaneously in healthy infants because of the very high transpulmonary pressures produced at birth. However, the incidence is much higher in the presence of underlying lung disease and in infants exposed to mechanical ventilation. Pneumothorax develops in 5% to 10% of spontaneously breathing infants with hyaline membrane disease. Although positive pressure ventilation increases the risk dramatically, treatment with surfactant has markedly lowered this risk.

Pneumomediastinum occurs when gas tracks through the perivascular and peribronchial cuffs to the hilum and then enters into the mediastinum. From there, gas can enter into the pleural space, producing a pneumothorax. If the leak is large, it produces a tension pneumothorax that collapses the lung and results in severe hypoxia and hypercapnia. In addition, by increasing intrathoracic pressure and compressing mediastinal structures, venous return to the heart may be impeded, resulting in circulatory compromise.

Because of the severe consequences of a tension pneumothorax, it is important to diagnose it as early as possible. In the spontaneously breathing infant, pneumothorax usually produces tachypnea, grunting, pallor, and cyanosis. The cardiac sounds may be shifted away from the side of the pneumothorax, and the affected hemithorax and abdomen may appear to be bulging. In the infant receiving positive pressure ventilation, the signs are frequently more dramatic, with sudden onset of hypoxemia and cardiovascular collapse (Ogata et al., 1976). Transillumination of the chest is positive over the affected side, and the pneumothorax is confirmed by chest radiograph that shows gas in the pleural space and partial collapse of the lung with a shift of the mediastinum to the opposite side (Fig. 45.8).

A small pneumothorax in a spontaneously breathing infant may be observed closely until spontaneous resolution occurs. Infants with larger symptomatic pneumothoraces and infants receiving positive pressure ventilation require thoracostomy and pleural tube

placement. The tube may be inserted at the midaxillary line and directed anteriorly or may be placed in the second intercostal space in the midclavicular line and directed toward the diaphragm so that the tip lies between the lung and the anterior chest wall. When placing the tube, the operator must avoid puncturing the lung, especially when a trocar, rather than a curved hemostat, is used to direct the tube. It also is possible to drain pneumothoraces with pigtail catheters that are placed percutaneously into the pleural space. This technique produces less trauma but may not be effective when large gas leaks are present. The thoracostomy tube is connected to a water seal with 10- to 20-cmH₂O negative pressure and is left in place until draining ceases. Application of the negative pressure should be discontinued, and the tube should be left under the water seal for 12 to 24 hours before removal to ensure that the gas leak has stopped.

Pneumopericardium

Pneumopericardium results from direct tracking of interstitial gas along the great vessels into the pericardial sac. Gas under tension in the pericardium can impair atrial and ventricular filling, decrease stroke volume, and ultimately decrease cardiac output and systemic blood pressure. Infants have increasing hypoxemia, decreased heart sounds, and decreased systemic blood pressure and pulse pressure. The chest radiograph is diagnostic, showing gas surrounding the cardiac silhouette (Fig. 45.9). Needle aspiration alleviates the acute symptoms, but because the recurrence rate is high, continuous tube drainage is necessary in most cases.

Pneumoperitoneum

Pneumoperitoneum results from dissection of air from the mediastinum along the sheaths of the aorta and vena cava into the peritoneal cavity. Infants with this condition experience sudden abdominal distention and have a typical abdominal radiograph. Occasionally, the pneumoperitoneum may be large enough to cause respiratory embarrassment by compromising descent of the diaphragm and may require drainage. This cause of peritoneal free gas must be distinguished from a primary gastrointestinal perforation, which is much more common.

• **Fig. 45.8** Tension Pneumothorax. The lung on the involved side is collapsed, and the mediastinum is shifted to the opposite side, with bulging of the pleura into the intercostal spaces.

• **Fig. 45.9** Pneumopericardium. A thin rim of pericardium is visible and clearly separated from the heart by gas within the pericardial sac.

Intravascular Gas

It has been suggested that the intravascular gas is pumped under high pressure through the pulmonary lymphatics into the systemic venous circulation (Booth et al., 1995). The intravascular gas results in immediate cardiovascular collapse and is often diagnosed when gas is seen in vessels or in the heart chambers when a chest radiograph is taken to determine the cause of cardiovascular collapse. Intravascular gas is usually a fatal complication.

Airway Complications

Prolonged endotracheal intubation can produce airway damage and subglottic stenosis. The risk is increased by a too snugly fitting ETT, prolonged duration of intubation, and traumatic intubation. Some infants may require tracheostomy and even surgery to repair the stenosis. Inadequate humidification of the inspired gas can produce necrotizing tracheobronchitis, a necrotic inflammatory process involving the trachea and main bronchi. Infants have acute respiratory deterioration due to airway obstruction, hyperexpansion on chest radiograph, and poor chest movement. Emergency bronchoscopy may be necessary to relieve airway obstruction.

Lobar or segmental atelectasis frequently occurs during prolonged ventilation and after extubation from mechanical ventilation. This can be secondary to airway injury due to trauma produced by suction catheters, by inadequate conditioning of the inspired gas, and by airway obstruction due to retained secretions.

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia is a very common complication of mechanical ventilation at any age, and it is likely to occur even more frequently in the immune-compromised premature infant. Unfortunately, it is not commonly diagnosed in this population because of the lack of specific criteria and the difficulty of differentiating pneumonia from other acute and chronic pulmonary diseases observed in infants requiring prolonged mechanical ventilation. Despite these limitations, it should be suspected whenever there is deterioration in lung function with radiographic changes suggestive of pneumonia. Change in the amount and quality of the secretions obtained from the airway and colonization with pathogens is another indication of possible pulmonary infection that may require antibiotic therapy.

Some evidence indicates that a large proportion of ventilated premature infants have aspiration of gastric contents into their airways. This is more common in fed infants and those receiving methylxanthines (Farhath et al., 2006). The consequences of this are not clear, but this could further contribute to the risk of pulmonary infection and chronic lung damage.

Ventilator- and Oxygen-Associated Neurologic Sequelae

Prolonged need for mechanical ventilation and oxygen supplementation has been associated with increased risk of NDI in premature infants (Collins et al., 2001; Walsh et al., 2005). Although these associations may be in part determined by the fact that infants with worse respiratory course are also those with worse neurologic outcome, there is a considerable amount of data suggesting that NDI may be in part mediated by excessive hyperoxia and hypocapnia or fluctuating arterial levels of oxygen and carbon dioxide (Fabres et al., 2007; Di Fiore et al., 2010; Pappas et al., 2011; Poets et al.,

2015). Periventricular white matter injury is among the causes of NDI in premature infants. Postmortem studies showed elevated levels of markers of oxidative stress and cellular damage in infants with periventricular leukomalacia (Haynes et al., 2003). The white matter vulnerability to oxidant damage in the preterm infant has been attributed to selective lipid peroxidation and death of oligodendrocyte progenitors (Back et al., 2005). As indicated by animal experiments, the interaction of these conditions with genetic and molecular mechanisms could lead to significant brain injury (Albertine et al., 2012).

Future Directions

Although neonatal respiratory support has advanced considerably in the last few decades, there are still numerous areas that need improvement.

Respiratory monitoring could be significantly enhanced by advances in noninvasive monitoring of blood gases, both arterial and venous, as well as monitoring of brain and organ oxygenation and perfusion and hemodynamics. A promising area is that of development of noninvasive methods to assess lung volume and perfusion that until this point have been limited to complex techniques that have been primarily used in research studies or invasive clinical procedures.

With increased awareness of the importance of adequate maintenance of oxygenation and ventilation, development of more reliable and smarter alarms could reduce alarm fatigue and increase staff attentiveness.

Noninvasive modes of support could be advanced by more patient-friendly yet effective interfaces as well as by the more general availability of simple techniques to provide synchronized ventilation to the extremely preterm infant.

Significant advances have already occurred in regard to automation of ventilatory support and oxygen supplementation. Still, there is a need to fully assess the impact and safety of these new devices on important neonatal outcomes. The availability of these automated systems may facilitate the determination of optimal oxygenation and ventilation levels for infants of different gestational and postnatal ages as well as for the different respiratory conditions.

Respiratory Disorders in the Preterm Infant

J. CRAIG JACKSON

KEY POINTS

- In extremely preterm newborns with respiratory distress, respiratory distress syndrome (RDS) is by far the most common diagnosis.
- The development of exogenous surfactant for treatment of RDS is one of the most important advances of newborn medicine.
- Despite widespread consensus on the antenatal use of steroids, controversies remain, including the type of steroid, the dose, frequency and timing, and the route of administration.
- Application of nasal continuous positive airway pressure (CPAP) started at or soon after preterm birth may be considered an alternative to routine endotracheal intubation with early surfactant administration.
- Severe hypercarbia immediately after birth suggests one of the following diagnoses: pulmonary hypoplasia, tension pneumothorax, congenital diaphragmatic hernia, or severe airway obstruction.
- When preterm prolonged rupture of membranes occurs at 15 weeks, the incidence of pulmonary hypoplasia is 80%; when it occurs at 19 weeks, the incidence is 50%, and when it occurs after 26 weeks, the incidence is nearly zero.
- Pulmonary hemorrhage occurs in 3%–5% of preterm infants needing respiratory support, usually at 1 to 3 days of age.

This chapter on respiratory distress in the preterm infant will focus primarily on RDS, also known as *hyaline membrane disease*. However, it also includes information about two less frequent causes: pneumonia/sepsis and pulmonary hypoplasia. Other causes of respiratory distress that are more commonly seen in term infants are briefly mentioned since they are discussed in greater depth in Chapter 47. Table 46.1 lists the most common causes of respiratory distress in newborns and demonstrates the relative frequency of each diagnosis. This table provides a useful differential diagnosis for respiratory distress in preterm neonates, but polycythemia and hypoglycemia should also be considered. More than half of extremely low birth weight newborns will have some type of respiratory distress (Fig. 46.1). In that population, RDS is by far the most common diagnosis (51%), followed by transient tachypnea of the newborn (TTNB; 4%) and pneumonia/sepsis (2%). In higher birth weight preterm newborns, the incidence of any type of respiratory distress is much lower, but the proportion with TTNB increases with higher

birth weight. Compared with the incidence of three diagnoses featured in Fig. 46.1, the incidence of other causes of respiratory distress (Table 46.1) is very low in preterm infants, but the causes should be considered in those newborns with an atypical clinical course.

Respiratory Distress Syndrome

Risk Factors

The main risk factor for RDS, by far, is prematurity (see Fig. 46.1). Other factors that increase the risk of RDS include perinatal asphyxia, maternal diabetes, absence of labor, absence of prenatal steroid administration to the mother, male sex, and white race. The central feature of RDS is surfactant deficiency due to lung immaturity, commonly a result of premature birth or delayed lung maturation associated with maternal diabetes or male sex. Surfactant dysfunction can also be caused by genetic abnormalities of surfactant-associated proteins, perinatal asphyxia, pulmonary infection, or excessive fetal lung liquid due to delivery without labor.

Pathophysiology of Respiratory Distress Syndrome

Because alveoli with insufficient (or dysfunctional) surfactant are unstable and tend to collapse, patients with RDS develop generalized atelectasis, ventilation–perfusion mismatching, and subsequent hypoxemia and respiratory acidosis.

During breathing (either spontaneous or assisted), shear stresses in the alveoli and terminal bronchioles occur because of the repetitive reopening of collapsed alveoli and the overdistention of open alveoli (Nilsson et al., 1978). These forces can quickly damage the fragile lung architecture, leading to leakage of proteinaceous debris into the airways (i.e., hyaline membranes). This debris (Fig. 46.2) may impair the function of what little surfactant is present, leading to a downward spiral that may end in respiratory failure and death if not interrupted.

If supportive therapy is successful, the repair phase usually begins during the second day after birth with the appearance of macrophages and polymorphonuclear cells (Jackson et al., 1987). Debris is phagocytosed, and the damaged epithelium is regenerated.

Edema fluid in the interstitium is mobilized into lymphatics, leading to the diuretic phase of RDS characterized by high urine output.

With uncomplicated RDS, the patient's condition improves by the end of the first week after birth. However, infants with a birth weight less than 1250 g and larger newborns needing high concentrations of oxygen and positive pressure ventilation

for severe RDS may develop inflammation and inappropriate repair of the growing lung, leading to emphysema and fibrosis (see Chapter 48).

Purpose of Surfactant

Surface tension is generated from molecular attractive forces within a liquid that oppose spreading; this is the reason that water “beads up” on a clean surface. If you try to inflate a bubble under water with a straw (Fig. 46.3A), the spreading of the water's surface and enlargement of its surface area will be opposed by its surface tension (T). According to Laplace's law, the pressure (P) required to inflate the bubble is proportional to T divided by the radius of the bubble (r). If you simultaneously try to inflate two interconnected bubbles, the smaller one will deflate into the larger one, because of its smaller radius (Fig. 46.3B).

Surfactants are surface-active materials that lower surface tension; a detergent is a type of surfactant that causes water to spread out on a surface rather than bead up. The surface tension of clean water resists the creation of bubbles, but the addition of detergent allows bubbles to form. Because the surfactant properties of detergents do not persist, all of the small bubbles in the foam eventually collapse into the large ones, and finally even the large ones collapse.

Lung surfactant has the miraculous property of reducing surface tension as the size of the bubble decreases. If the surface tension remained high, the pressure required to keep smaller alveoli open as their radius decreased would be greater than the pressure keeping open larger alveoli, so the small alveoli would collapse into larger ones, as shown in Fig. 46.3B. However, if the bubbles are lined with high-quality surfactant, the surface tension falls quickly as the radius gets smaller because the surfactant molecules become crowded during deflation (Fig. 46.4). When the radius is very small, the surface tension falls almost to zero, and the pressure required to keep the smaller bubble open is negligible, and thus it does not collapse.

During inflation, as the radius of each alveolus increases, surface tension increases even faster. This means that the pressure in the larger alveoli will be higher than that in smaller ones; in the lung

TABLE 46.1 Causes of Respiratory Distress

| Cause | Frequency % |
|--|-------------|
| Respiratory distress syndrome | 46 |
| Transient tachypnea of newborn | 37 |
| Pneumonia/sepsis | 5 |
| Meconium aspiration syndrome | 2 |
| Congenital cardiac malformation | 2 |
| Chromosomal disorder/multiple congenital anomalies | 1.4 |
| Spontaneous pneumothorax | 1.2 |

• **Fig. 46.3** Effect of Surface Forces Generated by Inflation of Bubbles Under Water. (A) A single bubble of radius r resists inflation and thus requires pressure P to overcome the surface tension T . (B) If the surface tension is the same in two bubbles of unequal size, the smaller one will collapse into the larger one, because of the Laplace relationship, $P = T/r$ (small r requires higher pressure for the bubble to stay inflated).

where alveoli are interconnected, this pressure difference will cause flow *to* the smaller alveoli, thus keeping all the alveoli about the same size.

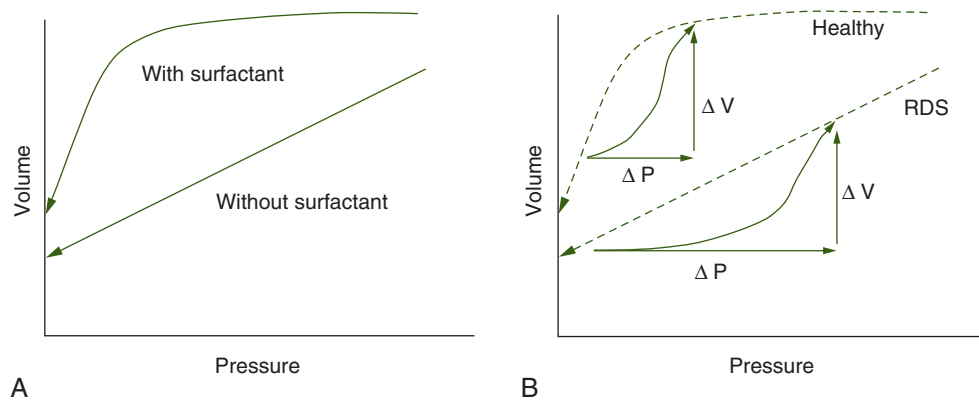

The cumulative result of the alveoli remaining open during deflation is a nonlinear pressure–volume relationship. The lung

with sufficient surfactant retains gas during expiration, compared with rapid and almost complete loss of gas in the surfactant-deficient lung (Fig. 46.5A). During inflation, more pressure is required to achieve a similar tidal volume (see Fig. 46.5B), because of poor compliance ($\Delta V/\Delta P$) from having to reopen collapsed alveoli. For instance, to achieve a tidal volume of 5 mL/kg, an infant with RDS may require a pressure increase of 25 cmH₂O; dividing the volume change, ΔV , by the pressure change, ΔP , we calculate that the compliance is only 0.25 mL/kg per centimeter of water, which is about one-third of normal.

In the absence of adequate amounts of functional surfactant in the newborn lung, there is widespread alveolar collapse with

• **Fig. 46.5** Effect of Surface Forces on Pressure-Volume Relationships. During deflation (A) the lungs with surfactant retain gas even at very low pressures, because of falling surface tension as the alveoli get smaller. The alveoli without surfactant collapse as they get smaller. During inflation of respiratory distress syndrome (RDS) lungs (B), the starting lung volume (functional residual capacity) is lower, and much more pressure is required during inflation, compared with healthy lungs.

overdistention of open alveoli (Fig. 46.6). Because reopening collapsed alveoli requires high pressure, the spontaneously breathing newborn with surfactant deficiency must generate highly negative intrathoracic pressure. Clinically, this is manifested by retractions of the chest wall and use of accessory muscles during inspiration. Newborns may also attempt to prevent alveolar collapse by grunting. This partial closure of the glottis during expiration helps maintain an end-expiratory pressure that may keep some unstable alveoli open.

A consequence of widespread alveolar collapse is intrapulmonary shunting of blood past nonaerated lung tissue, without the opportunity for blood in pulmonary capillaries to pick up oxygen from, or deliver carbon dioxide to, the alveoli. In addition, lungs that are poorly inflated have partially collapsed intrapulmonary vessels, leading to pulmonary hypertension. The elevated pulmonary artery pressures lead to right-to-left shunting of unoxygenated blood across the patent ductus arteriosus to the descending aorta (see Chapter 52).

Origin and Composition of Surfactant

Pulmonary surfactant is composed of approximately 90% lipids and 10% proteins. The main phospholipid in surfactant is dipalmitoylphosphatidylcholine (DPPC), also known as *lecithin*. It is surface active because of its hydrophilic head and hydrophobic tails (Fig. 46.7). However, DPPC by itself does not adsorb efficiently at the air-liquid interface and is in the form of a gel at body temperature. The presence of some unsaturated phospholipids and cholesterol helps to make it more fluid (Mingarro et al., 2008).

The other main ingredients of surfactant are shown in Fig. 46.8. One of them, phosphatidylglycerol, is sometimes used as a marker of lung maturation; it interacts with the hydrophobic surfactant proteins to increase biophysical activity. Even minor components of pulmonary surfactant play important roles; for instance, free fatty acids increase the stability of the interfacial film, especially after repeated compression. The composition of surfactant is complex because it has evolved to balance the need for low viscosity for optimal spreading and redistribution along the smallest airways with the need for a stable and low surface tension.

Surfactant phospholipids are assembled in the type II pneumocytes of the lung epithelium into lamellar bodies in the form

• **Fig. 46.6** Histology of Respiratory Distress Syndrome. Scanning electron micrograph of lung frozen during inflation with air in a healthy premature monkey (A) compared with one with respiratory distress syndrome (B). Lungs affected by respiratory distress syndrome have collapsed alveoli full of liquid and proteinaceous debris, with overdistended terminal airways. From Jackson JC, Truog WE, Standaert TA, et al: Effect of high-frequency ventilation on the development of alveolar edema in premature monkeys at risk for hyaline membrane disease, *Am Rev Respir Dis* 143:865–871, 1991. The *American Review of Respiratory Disease* is an official journal of the American Thoracic Society.)

of bilayer membranes (Fig. 46.9). Surfactant-associated protein B (SP-B) and surfactant-associated protein C (SP-C) are essential for the transition to a monolayer at the air–liquid interface. The molecular structure of the hydrophobic SP-B is complex, and it interacts with the phospholipid monolayer as shown in Fig. 46.10. Its absence is associated with fatal neonatal respiratory failure. Surfactant-associated protein A and surfactant-associated protein D are hydrophilic and have roles in immune defense. Surfactant-associated protein A is also involved in reuptake and reuse of secreted surfactant (see Chapter 42).

Clinical Signs of Respiratory Distress Syndrome

The cardinal clinical signs of RDS are tachypnea, grunting, and increased work of breathing (Box 46.1). The respiratory rate is elevated in an attempt to increase the exchange of oxygen and carbon dioxide, but with exhaustion, the rate may decline or even become zero. The newborn may grunt to create positive pressure in the lungs in an attempt to prevent collapse of air sacs. Signs of increased work of breathing include nasal flaring and retraction of the chest wall from vigorous use of the intercostal and subcostal muscles and use of accessory muscles in the neck. Because the rib cage in premature infants is so flexible, the sternum may deeply retract during inspiration, with abdominal distention, leading to a “see-saw” type of respiration. Cyanosis results from inadequate

oxygenation, and pallor results from acidosis due to poor elimination of carbon dioxide. The combination of increased work of breathing, cyanosis, and acidosis causes lethargy and disinterest in feeding and eventually apnea. Rather than progressing through these signs during the first hours of life, newborns with intrapartum asphyxia or extreme prematurity may have apnea immediately after birth.

On auscultation, breath sounds may be distant or shallow from the fast inspiratory rate and low tidal volume, and fine inspiratory rales may be heard because of the reopening of moist, collapsed small airways. The onset of symptoms is always within hours after birth and, in severe cases, may occur with the first few breaths after delivery. In general, the respiratory distress from RDS tends to get worse in the first 1 to 3 days after birth and then usually abates gradually in a few days (although the natural course may be interrupted by exogenous surfactant therapy or application of CPAP).

Differential Diagnosis

Clinical improvement during the first 12 hours after birth suggests TTNB, whereas onset of respiratory distress after the first 24 hours suggests pneumonia and sepsis. Tachypnea without increased work of breathing suggests cyanotic heart disease; the diagnosis of obstructed pulmonary veins from total anomalous venous return is occasionally confused with RDS. Hypoventilation without increased work of breathing suggests a central nervous system problem such as intracranial hemorrhage or asphyxia. Asymmetric breath sounds may be due to pneumothorax (which is a complication of RDS), congenital diaphragmatic hernia, or unilateral pleural effusion. Meconium staining of amniotic fluid suggests the possibility of meconium aspiration syndrome, but this is rare in premature infants—green-stained amniotic fluid in this population is more likely to be due to bile refluxed into the esophagus because of intestinal obstruction rather than meconium.

• **Fig. 46.11** Radiograph of a patient with respiratory distress syndrome. Note low lung volumes and a reticulogranular pattern. (From Welty S, Hansen TN, Corbet A. Respiratory distress in the preterm infant. In: Taeusch HW, Ballard RA, Gleason CA, eds. *Avery's Diseases of the Newborn*. 8th ed. Philadelphia, PA: Elsevier; 2005:687–703.)

Laboratory Features of Respiratory Distress Syndrome

Initially the arterial blood gases will show hypoxemia, and the oxygen saturation monitor will show desaturation unless supplemental oxygen is provided. PaCO_2 may be normal because of tachypnea but is almost always elevated. Later, as the infant tires, PaCO_2 will rise further and cause respiratory acidosis. With imminent respiratory failure, there may be progressive metabolic acidosis due to inadequate oxygen delivery to tissues from poor peripheral perfusion.

Differential Diagnosis

Extremely elevated PaCO_2 within minutes of birth suggests pulmonary hypoplasia, tension pneumothorax, congenital diaphragmatic hernia, or obstruction of the airways due to debris or an anatomic cause. The tachypneic, cyanotic newborn with low PaCO_2 may have TTNB or cyanotic congenital heart disease. A positive blood culture result suggests pneumonia and sepsis. Low blood glucose level (<40 mg/dL) suggests symptomatic hypoglycemia, and high hematocrit ($>65\%$) suggests symptomatic polycythemia (Uslu et al., 2011).

Radiographic Features of Respiratory Distress Syndrome

The classic radiographic findings of RDS include a reticulogranular (i.e., ground-glass) pattern and air bronchograms (Fig. 46.11). The lungs are diffusely and homogeneously dense because of widespread collapse of alveoli. The appearance is reticular (i.e., netlike) because the small airways are open (black) and surrounded by interstitial and alveolar fluid (white); in severe cases the lungs may appear completely white on the film. Air bronchograms are commonly seen because the large airways beyond the second or third generation are more visible than usual as a result of radiodensity

• BOX 46.2 Initial Diagnostic Evaluation for Possible Respiratory Distress Syndrome

Arterial or capillary blood gas

Echocardiogram (if clinically indicated)

from engorged peribronchial lymphatics and fluid-filled or collapsed alveoli. Another cardinal feature is low lung volume (e.g., the diaphragms are at the eighth rib level or higher) due to widespread alveolar collapse and low functional residual capacity.

Differential Diagnosis

Normal or high lung volumes, especially with prominent interstitial fluid pattern, suggest TTNB. In this case there are coarse white lines (engorged lymphatics and interstitial water) radiating from the hilum rather than the crisp black lines (air bronchograms) of RDS. Other causes of a coarse (rather than diffuse) fluid pattern include pneumonia with sepsis and obstructed pulmonary venous drainage due to total anomalous pulmonary venous return. An abnormal cardiac silhouette or size should suggest congenital heart disease, and asymmetry of the lungs suggests pneumothorax, congenital diaphragmatic hernia, or congenital pulmonary airway malformation. Very low lung volumes, especially when accompanied by pneumothorax, may indicate pulmonary hypoplasia.

Initial Diagnostic Evaluation for Possible Respiratory Distress Syndrome

The initial diagnostic evaluation (Box 46.2) is shaped by the differential diagnoses listed in Table 46.1 and by the urgency to intervene quickly for serious but infrequent conditions such as bacterial pneumonia and sepsis, hypoglycemia, and polycythemia. It is often helpful to obtain both anteroposterior and lateral radiographs for the initial evaluation. If congenital heart disease is suspected on clinical grounds, an echocardiogram is indicated.

Treatment of Patients With Respiratory Distress Syndrome

The treatment of patients with RDS is outlined in Box 46.3. All patients with RDS need the basics of warmth, hydration, and nutrition appropriate for the degree of prematurity, as described in other chapters. Because pulmonary edema contributes to surfactant dysfunction in RDS, it is important to avoid excessive intravenous fluid administration.

Newborns with significant tachypnea (e.g., more than 60 breaths per minute) or increased work of breathing (moderate or severe) often do not have the energy required for oral feeding, and there is some risk of aspiration if nipple feeding is attempted. Initially, administration of intravenous fluids and nothing by mouth status may be appropriate, with consideration of small gavage tube gastric feedings if the baby is otherwise stable. Parenteral nutrition may be indicated because of the increased caloric expenditures associated with work of breathing. Administration of antibiotics should be considered unless the risk of pneumonia and sepsis is negligible

• BOX 46.3 Treatment of Established Respiratory Distress Syndrome

Warmth by radiant warmer or incubator
Hydration at approximately 60–80 mL/kg per day
Nutrition
Initially D5W or D10W (with protein, if possible)
Nothing by mouth if respiratory rate more than 60 breaths per minute or if moderate/severe work of breathing
Gavage feeds if stable
Consider parenteral nutrition if enteral feeds are delayed
Antibiotics if at risk of pneumonia and sepsis
Supplemental oxygen
Oxygen saturation monitoring, with appropriate target for infants at risk of retinopathy of prematurity
Exogenous surfactant
CPAP or mechanical ventilation, as needed

CPAP, Continuous positive airway pressure; D5W, dextrose 5% in water; D10W, dextrose 10% in water.

(e.g., premature delivery for maternal indications with no risk factors for chorioamnionitis).

Because exogenous surfactant and CPAP are used for both prevention and treatment of RDS, they are described in the Prevention and Treatment of Respiratory Distress Syndrome section below. See Chapter 45 regarding the risks and benefits of different modes of respiratory therapy.

Respiratory Complications of Respiratory Distress Syndrome

Air leak complications occur in patients with RDS because of the asymmetry of alveolar inflation and the sheer stresses in terminal bronchioles, leading to dissection of air into the interstitium (causing pulmonary interstitial emphysema) and through the visceral pleura (causing pneumothorax). The former can be seen in up to 50% of patients with RDS, and the latter can be seen in 5%–10%, even in those treated with exogenous surfactant.

Pulmonary hemorrhage occurs in about 3% of preterm infants needing respiratory support (Scholl and Yanowitz, 2015). For more information, see Pulmonary Hemorrhage at the end of this chapter.

Bronchopulmonary dysplasia (BPD), also known as *chronic lung disease*, may be exacerbated by abnormal lung repair following lung injury from RDS in the setting of interrupted normal lung development compounded by lung inflammation (see Chapter 48).

Prevention and Treatment of Respiratory Distress Syndrome

Prenatal administration of steroids was shown in 1972 to be effective in reducing the risk of RDS (Liggins and Howie, 1972). A consensus panel convened by the National Institutes of Health concluded that “antenatal corticosteroid therapy is indicated for women at risk of premature delivery with few exceptions and will result in a substantial decrease in neonatal morbidity and mortality, as well as substantial savings in health costs” (NIH Consensus Development Panel on the Effect of Corticosteroids for Fetal Maturation on Perinatal Outcomes, 1995). It recommended that the treatment be used from 24 to 34 weeks’ gestation without limitation by sex or race and whether or not surfactant therapy was available. Although the beneficial effects were found to be greatest if treatment was begun more than 24 hours before delivery, there was also a

benefit when treatment was given for less than 24 hours. Recently, it has been shown to be beneficial to late preterm infants delivered before 37 weeks' gestation (Gyamfi-Bannerman et al., 2016).

A review of 21 published trials (Roberts and Dalziel, 2006) concluded that prenatal administration of corticosteroids did not increase a mother's risk of death, chorioamnionitis, or puerperal sepsis. Treatment was associated with a 31% reduction in neonatal death, 34% reduction in RDS, 46% reduction in cerebroventricular hemorrhage, and 54% reduction in necrotizing enterocolitis (all significant at $P \leq .05$). In a metaanalysis, Brownfoot et al. (2013) reviewed 12 trials and found that prenatal administration of dexamethasone appears to decrease the incidence of intraventricular hemorrhage without reducing the incidence of RDS or perinatal death. Although there is now widespread consensus on the antenatal use of steroids, some issues remain controversial, including the type of corticosteroid to use; the dose, frequency, and timing of use; and the route of administration.

Because the effectiveness appears to wane if steroids are given more than 1 week before premature delivery, several trials have been conducted to determine whether one or more repeated doses at weekly intervals are beneficial. Although a metaanalysis (Crowther and Harding, 2007) found modest reductions in the occurrence and severity of RDS, there were concerning findings of lower birth weight and smaller head circumference, indicating that there is insufficient evidence to recommend repeated doses (Bonanno and Wapner, 2009). An international randomized clinical trial did not find differences in the risk of death or disability at 5 years of age when comparing multiple course of steroids administered prenatally with a single course (Asztalos et al., 2013).

Prevention of Asphyxia

Prevention of asphyxia may decrease the incidence and severity of RDS, because asphyxia leads to hypoxemia and acidosis, which reduce surfactant synthesis. Leakage of fluids from capillaries into alveoli may also impair surfactant function. Premature infants are at much higher risk of needing intervention at birth, and thus preparation and staffing for full neonatal resuscitation are necessary. Maternal transfer to a center experienced in management of premature infants is associated with improved neonatal outcome.

Continuous Positive Airway Pressure

Gregory et al. (1971) first introduced CPAP therapy for newborns with RDS, primarily by an endotracheal tube. Since then a variety of devices have been developed, including short nasal prongs that do not add much to the work of breathing (De Paoli et al., 2002). For more information on the principles and use of CPAP therapy, see Chapter 45. Avery et al. (1987) reported that centers that used early nasal CPAP therapy for RDS had a lower incidence of BPD, and now CPAP is well established as the most common respiratory therapy for prevention and treatment of respiratory distress in premature infants.

The goals of CPAP therapy in preterm infants at risk of respiratory failure are to prevent end-expiratory alveolar collapse, reduce the work of breathing, and better match ventilation to perfusion. If it is started in the delivery room, it may help the newborn establish functional residual capacity, in addition to stabilizing the chest wall and reducing airway resistance. Furthermore, adequate expansion of the lungs at birth increases pulmonary blood flow. The prophylactic use of CPAP in the delivery room might make intubation for exogenous surfactant unnecessary (De Klerk and De Klerk, 2001), and avoidance of intubation and mechanical ventilation may lower the risk of BPD.

The COIN trial randomized 25 to 28 weeks' gestation newborns who were breathing spontaneously at 5 minutes of age to receive either CPAP or prophylactic intubation with early extubation to CPAP if possible. The investigators found that 46% of the CPAP group eventually required intubation anyway during the first 5 days, and the rate of pneumothorax was 9%, compared with only 3% in those intubated routinely ($P < .001$) (Morley et al., 2008). However, a metaanalysis (Schmölzer et al., 2013) concluded that one additional infant could survive to 36 weeks without BPD for every 25 babies treated with nasal CPAP therapy in the delivery room rather than being intubated.

Some centers report use of humidified high-flow nasal cannulas in infants with RDS (Lampland et al., 2009) to achieve the benefits of positive airway pressure with fewer of the perceived disadvantages of CPAP (challenges in keeping the nasal prongs in the nares, more difficult handling of the patient, and greater risk of pressure necrosis of the nasal septum). However, the airway pressure generated from this therapy, although proven to produce a clinical effect, is variable, unpredictable, and unregulated, and the commercially available systems are not approved by the US Food and Drug Administration for this indication. It should be used only by practitioners aware of the balance of risks and benefits and those prepared to recognize and treat pneumothorax and respiratory failure. A recent review outlines the main advantages and disadvantages of the many types of CPAP delivery devices, as well as implications for developing countries (Gupta et al., 2015).

Exogenous Surfactant

Historical Summary

The development of exogenous surfactant for treatment of RDS is one of the most important advances in the history of newborn medicine. This history is well told elsewhere (e.g., Halliday, 2008). The key milestones include von Neergaard's discovery in 1929 that surface tension contributes to lung recoil, Gruenwald's demonstration in 1947 that lungs of stillborn infants have high surface tension, Prattle's speculation in 1955 that absence of surfactant active material contributes to RDS, Clement's description in 1957 of surfactant dysfunction in experimental animals, and Avery and Mead's demonstration in 1959 that RDS in human infants is due to surfactant deficiency. There was an increase in research interest and funding for RDS treatment after President Kennedy's son, born at 34.5 weeks' gestation, died of RDS in 1963. In 1972, Enhorning and Robertson used natural surfactant to delay the progression of RDS in preterm rabbits, and in 1980 Fujiwara et al. demonstrated the first successful use of exogenous surfactant in human infants. By 1990, exogenous surfactant was widely used throughout the developed world, and many large clinical trials have been conducted since then to refine and improve surfactant treatment and prevention of RDS. A metaanalysis of 13 randomized controlled trials suggests that animal-derived exogenous surfactant compared with standard therapy without surfactant reduces the risk of pneumothorax by 58%, the risk of pulmonary interstitial emphysema by 55%, the risk of death by 32%, and the risk of the combined outcome of BPD or death by 17% (Seger and Soll, 2009). However, the "standard therapy" did not include use of CPAP started immediately after birth (see later comments).

Types of Surfactants Available for Clinical Use

A list of currently available surfactant preparations and sources can be found in Table 46.2. The first generation of commercially available artificial surfactants (e.g., colfosceril [Exosurf]) was composed mainly of DPPC and did not have SP-B or SP-C.

TABLE 46.2 Commercially Available Surfactant Preparations and Their Sources

| Brand Name | Generic Name | Constituents | Amount per Dose |
|---|-------------------|---------------------------|------------------------------|
| Protein-Containing Animal Surfactants | | | |
| Curosurf | Poractant alfa | Porcine lung tissue | 2.5 mL/kg (redose 1.5 mL/kg) |
| Infasurf | Calactant CLSE | Bovine (calf) lung lavage | 3 mL/kg |
| Survanta | Beractant | Bovine lung tissue | 4 mL/kg |
| Peptide-Containing Synthetic Surfactants | | | |
| Surfaxin | Lucinactant | DPPC, POPG, PA, KL4 | 5.8 mL/kg |

CLSE, calf lung surfactant extract; DPPC, dipalmitoylphosphatidylcholine; PA, palmitic acid; POPG, palmitoyloleoylphosphatidylglycerol.
Modified from Walsh BK, Daigle B, DiBlasi RM, Restrepo RD. AARC clinical practice guideline. Surfactant replacement therapy: 2013. *Respir Care*. 2013;58:367–375.

However, a metaanalysis of 11 randomized controlled trials showed that natural surfactants were faster acting than artificial surfactants, with lower incidence of pneumothorax and death (Soll and Blanco, 2001). Work continued on development of synthetic surfactants to lower the cost and because of theoretical concerns about immunologic or infectious complications from animal-derived surfactant. These newer products have synthetic peptides or proteins, such as KL4 in lucinactant, which mimics the actions of natural SP-B and SP-C.

Surfactant Selection

The important issue for clinical providers and managers is which surfactant to stock in their pharmacy because of the expense of the preparations and the need to standardize dosing guidelines. A recent metaanalysis of clinical trials (Ardell et al., 2015) indicated that use of animal-derived surfactants leads to greater early improvement in ventilator support, fewer pneumothoraces, and fewer deaths when compared with use of artificial surfactants but may be associated with greater risk of necrotizing enterocolitis and grade 1 and grade 2 intraventricular hemorrhage. The most commonly used animal-derived surfactants that are commercially available include poractant alfa (from minced porcine lung; Curosurf) and beractant (from minced bovine lung; Survanta). A recent metaanalysis of clinical trials comparing these two drugs for prevention of RDS or treatment of RDS in premature infants at risk of or having RDS suggested that treatment with poractant alfa is associated with lower risk of death, BPD, and clinically significant patent ductus arteriosus and reduced need for repeated dosing (Singh et al., 2015). Poractant alfa also has the advantage of being more concentrated than beractant, and thus the lower volume of tracheal administration can be an advantage when larger and older newborns are dosed.

Timing of Surfactant Administration

In theory, surfactant would ideally be given with the first breath. This concept was evaluated by Kattwinkel et al. (2004) by delivering the head of the infant, suctioning the nasopharynx, and then instilling calfactant into the airway before delivery of the shoulders. CPAP therapy was initiated immediately after delivery, but the trachea was not routinely intubated. The treatment appeared feasible and safe, but the sample size (23) was too small to prove that the approach was beneficial compared with surfactant instillation via

an endotracheal tube during the first few minutes after delivery. Some have proposed administration of surfactant into the pharynx before the first breath in extremely preterm infants at high risk of RDS, but no clinical trials have been published yet (Abdel-Latif and Osborn, 2011). Preliminary clinical trials suggest that surfactant can be successfully aerosolized or nebulized (Pillow and Minocchieri, 2012), but as yet no benefits have been demonstrated in preterm infants with respiratory distress (More et al., 2014). However, work in animal models of preterm infants with RDS is encouraging (Walther et al., 2014).

Prophylactic surfactant generally refers to the administration of doses within the first 15 minutes after birth. To avoid giving an unnecessary, expensive medication and subjecting a newborn to the risks of tracheal intubation, prophylactic endotracheal surfactant should ideally be given only to patients who would have eventually developed RDS and met the treatment criteria for surfactant anyway. Several studies have compared “early” surfactant administration in infants intubated within 2 hours of delivery for respiratory distress with “rescue” surfactant administration in infants with established RDS, usually at several hours of age. Those receiving early surfactant therapy had decreased risk of pneumothorax and pulmonary interstitial emphysema and decreased risk of neonatal death and BPD (Bahadue and Soll, 2012). The benefits of early, prophylactic surfactant in older clinical trials of very preterm infants appear to have disappeared in the modern era of greater antenatal use of steroids and routine use of CPAP in the delivery room (Rojas-Reyes et al., 2012).

Combining and Comparing Surfactant Therapy With the Use of Continuous Positive Airway Pressure

Because of advances in the use of CPAP since the first clinical trials of surfactant, immediate extubation to CPAP after surfactant dosing (Verder et al., 1999) was proposed to limit complications from the endotracheal tube (including excessive tidal volumes and airway inflammation that may lead to BPD). This approach is now commonly referred to as the intubation, surfactant, and extubation (InSurE) technique. However, currently available studies are underpowered to ascertain whether this method is superior to use of nasal CPAP alone (Isayama et al., 2015).

Because of continuing concerns that even the brief period of endotracheal intubation for the InSurE method is risky and possibly associated with BPD, there have been several clinical trials comparing the InSurE method with administration of surfactant through a small endotracheal catheter while CPAP is being received, sometimes referred to as *less invasive surfactant application* (Kribs et al., 2015) or *minimally invasive surfactant therapy* (Aguar et al., 2014). Although the findings of small studies are encouraging, a recent metaanalysis did not find a difference in mortality or incidence of BPD compared with use of CPAP alone (Ali et al., 2016). The studies were underpowered to detect anything other than very large differences.

A recent policy statement from the American Academy of Pediatrics states that current evidence indicates that, for preterm infants, CPAP started at or soon after birth may be considered as an alternative to routine intubation with prophylactic or early surfactant administration (Carlo et al., 2014). The policy is based in part on the outcome of a large study known as the Surfactant Positive Pressure and Pulse Oximetry Randomized Trial (SUPPORT), which was designed to compare nasal CPAP started immediately after birth with prophylactic surfactant given within 60 minutes after birth in newborns at 24 to 27 weeks' gestation (Finer et al., 2010). There was no difference in the rate of death or BPD in the

TABLE 46.3 Delivery Room Respiratory Management of Preterm Infants

| Situation | Treatment |
|--|--|
| Not breathing at birth | Provide PPV with T-piece until breathing spontaneously. |
| ≤28 weeks' gestation <i>or</i> moderate-to-severe retractions at any gestational age | Initiate nasal CPAP at 5 cmH ₂ O as soon as possible, and titrate up to 8 cmH ₂ O as needed to reduce work of breathing and FiO ₂ . |
| Heart rate persistently <100 beats per minute <i>or</i> hemodynamic instability despite PPV or oxygen requirement >70% with CPAP <i>or</i> persistent apnea for >5 min | Intubate if necessary for resuscitation and then consider exogenous surfactant if requiring >30% oxygen and chest radiograph suggestive of RDS. |
| Improving FiO ₂ and reduced work of breathing | Extubate to nasal CPAP. |

CPAP, Continuous positive airway pressure; FiO₂, fraction of inspired oxygen; PPV, positive pressure ventilation; RDS, respiratory distress syndrome.

two groups. However, for babies born at 24 to 25 weeks' gestation, those in the CPAP group had lower mortality (20% vs. 29%, $P = .01$), and thus use of CPAP may be superior to the prophylactic surfactant strategy, despite the observation that two-thirds of the CPAP group eventually received surfactant anyway. At a corrected age of 18 to 22 months, there was less respiratory morbidity in those treated with early CPAP therapy rather than intubation/surfactant (Stevens et al., 2014).

Given the rapid evolution in published evidence contrasting and combining CPAP therapy and surfactant therapy, it is difficult to give firm recommendations on their use in preventing and treating respiratory distress in premature infants. However, most studies suggest that for either therapy to work most effectively in improving survival and reducing morbidity, they should be started as soon as possible. Furthermore, the duration of endotracheal intubation should be kept to a minimum, and endotracheal intubation should be avoided if possible. General strategies for management in the delivery room are offered in Table 46.3.

Methods of Surfactant Dosing

Animal studies suggest that surfactant is better distributed when administered as a bolus rather than by slow infusion in several minutes (Fernandez-Ruano et al., 1998). The package inserts of many surfactant preparations recommend moving the infant into multiple positions for better distribution of surfactant, but there are no clinical trials supporting one particular method. Therefore surfactant should be given as quickly as tolerated, with alveolar recruitment techniques, and with the least disruptive infant positioning (Nouraeian et al., 2014).

Number of Surfactant Doses and Dosing Intervals

A metaanalysis of two clinical trials that compared one dose versus multiple doses of animal-derived surfactant suggests a 49% reduction in the incidence of pneumothorax and a trend toward a 37% reduction in mortality when multiple doses are used (Soll and Ozek, 2009). There are no data to suggest that dosing should continue once the patient's ventilator and oxygen requirements are at minimal levels, or beyond four doses. The interval between

doses is usually at least 6 hours, and most research protocols discontinue dosing after 48 hours. Late treatment with up to five doses of surfactant in ventilated premature infants receiving inhaled nitric oxide was well tolerated but did not improve survival without BPD (Ballard et al., 2016).

Clinical Care After Dosing

Because natural surfactants may work quickly, the clinician must be prepared after dosing to immediately lower FiO₂ while carefully monitoring the pulse oximeter. The tidal volume, as measured by the ventilator and/or by careful observation of chest wall movement, may gradually increase, resulting in a need to lower inspiratory pressures to avoid air leak syndrome, lung injury, and possibly pulmonary hemorrhage. Blood gases and oxygen saturation should be monitored transcutaneously and/or by intermittent blood sampling. Positive end-expiratory pressure should be maintained but may be reduced if the starting levels were high, given that functional residual capacity increases shortly after surfactant administration.

A poor response to exogenous surfactant may occur because the patient does not have surfactant deficiency but rather has lung hypoplasia, pneumonia, or congenital heart disease. Other causes for a lack of response may be poor distribution of the surfactant, such as administration down the right stem bronchus due to malposition of the endotracheal tube, plugging of the tube, or malposition of the tube in the esophagus. A less likely reason is an inadequate dose of surfactant.

The rapid improvement in lung compliance after exogenous surfactant therapy may lead to excessive pulmonary blood flow from left-to-right shunting from a patent ductus arteriosus (Raju and Langerberg, 1993). It is uncertain whether early and aggressive intervention to close the ductus with medication or surgery will reduce the risk of pulmonary hemorrhage.

Pulmonary Hypoplasia

Definition and Incidence

One or both lungs of newborns with pulmonary hypoplasia are smaller than normal, including reduced numbers of lung cells, airways, blood vessels, and alveoli. Pulmonary hypoplasia is the cause of respiratory distress at birth in only 0.3% of newborns with respiratory symptoms (Rubaltelli et al., 1998), but it is commonly fatal, especially in preterm infants. The incidence is about 1 per 1000 live births, and 90% of cases are associated with congenital anomalies or pregnancy complications (De Paepe et al., 2005). There is a continuum of severity of pulmonary hypoplasia—from negligible to severe—and therefore all but the most severe cases are difficult to diagnose. This is especially true when one is attempting to diagnose pulmonary hypoplasia prenatally by imaging studies but is also true during clinical assessment of the newborn and even after postmortem examination of the lungs.

When one is considering the causes of pulmonary hypoplasia, it is useful to categorize them into associated conditions, each with representative diagnoses, as in Table 46.4. This chapter on respiratory distress in preterm infants focuses on the problem of pulmonary hypoplasia associated with oligohydramnios from preterm premature rupture of membranes because this cause of pulmonary hypoplasia occurs almost exclusively in preterm infants. When preterm premature rupture of membranes occurs at 15 weeks' gestation, the incidence of pulmonary hypoplasia is 80%, and when it occurs at 19 weeks, the incidence is 50%, whereas

TABLE 46.4 Categories of Conditions Associated With Pulmonary Hypoplasia

| Category | Representative Diagnoses |
|--|---|
| Restriction of thoracic space | Diaphragmatic hernia or eventration Intrathoracic mass Congenital cystic adenomatoid malformation Bronchogenic cyst Extralobar sequestration Thoracic neuroblastoma Pleural effusions Chylothorax Hydrothorax |
| Oligohydramnios | Renal Bilateral renal agenesis or dysplasia Bladder outlet obstruction (posterior urethral valves) Nonrenal Prolonged preterm rupture of membranes |
| Skeletal anomalies | Chondroectodermal dysplasia Osteogenesis imperfecta Thanatophoric dwarfism |
| Hydrops fetalis | Rhesus isoimmunization |
| Neuromuscular and central nervous system anomalies | Fetal akinesia Anencephaly Arnold–Chiari malformation |
| Cardiac anomalies | Hypoplastic right or left side of the heart Pulmonary stenosis Ebstein anomaly |
| Abdominal wall defects | Omphalocele Gastroschisis |
| Syndromes | Trisomy 13, 18, 21 Larsen syndrome Cerebrocostomandibular Jarcho–Levin syndrome Roberts syndrome Lethal multiple pterygium |

Modified from Langston C. Pulmonary Disorders in the Neonate, Infant, and Child. In: Churg AM, Myers JL, Tazelaar H, Wright J, eds. *Thurbeck's Pathology of the Lung*. 3rd ed. New York, NY: Thieme; 2005.

after 26 weeks the incidence is near zero (Rothschild et al., 1990). Other conditions associated with pulmonary hypoplasia are covered in other chapters.

Pathology

The easiest method of defining pulmonary hypoplasia during postmortem examination is to calculate the ratio of lung weight to body weight. At 28 weeks' gestation, a ratio of 0.015 is at the fifth percentile, whereas at 35 weeks' gestation, the fifth percentile is at a ratio of 0.012. The lung weight to body weight ratio may be artificially elevated if the lungs are wetter than usual from edema, hemorrhage, inflammation, or lymphangiectasia, and this may lead to the false conclusion that the patient does not have pulmonary hypoplasia. Conversely, the ratio may be artificially low if the body is heavier than usual because of renal cystic disease, hydrops, ascites, tumors, hydrocephaly, and so forth. Therefore a better method for postmortem diagnosis of pulmonary hypoplasia

is to measure the lung volume by inflating the lung at physiologic pressure and then measuring the displacement of fluid when the lung is immersed. The average lung volume is 33 mL/kg of body weight from 16 to 31 weeks' gestation, but it falls to 23 mL/kg at term (De Paepe et al., 2014). This method facilitates comparison of postmortem estimates with in utero estimates of lung volume made during prenatal imaging. However, low lung volume does not necessarily correlate with deficiency of lung structure and function. A postmortem technique more physiologically relevant than lung volume is the radial alveolar count, which is proportional to alveolar surface complexity (De Paepe et al., 2005) and thus gas exchange surface area; however, this procedure is complex and time consuming.

Impairment of lung development before 16 weeks causes reduced airway branching, reduced cartilage development, reduced acinar complexity and maturation, delayed vascularization, and delayed thinning of the air–blood barrier (see Chapter 42). Impairment after 16 weeks typically causes reduced acinar complexity and maturation. These outcomes are predictable, given the time in gestation when these structures are developing (Fig. 46.12A).

Because the growth of lung blood vessels parallels the development of the airways, pulmonary hypoplasia causes decreased total size of the pulmonary vascular bed, decreased number of vessels per unit of lung tissue, and increased amount of pulmonary artery smooth muscle. This last phenomenon accounts for persistent pulmonary hypertension after birth.

Clinical Signs

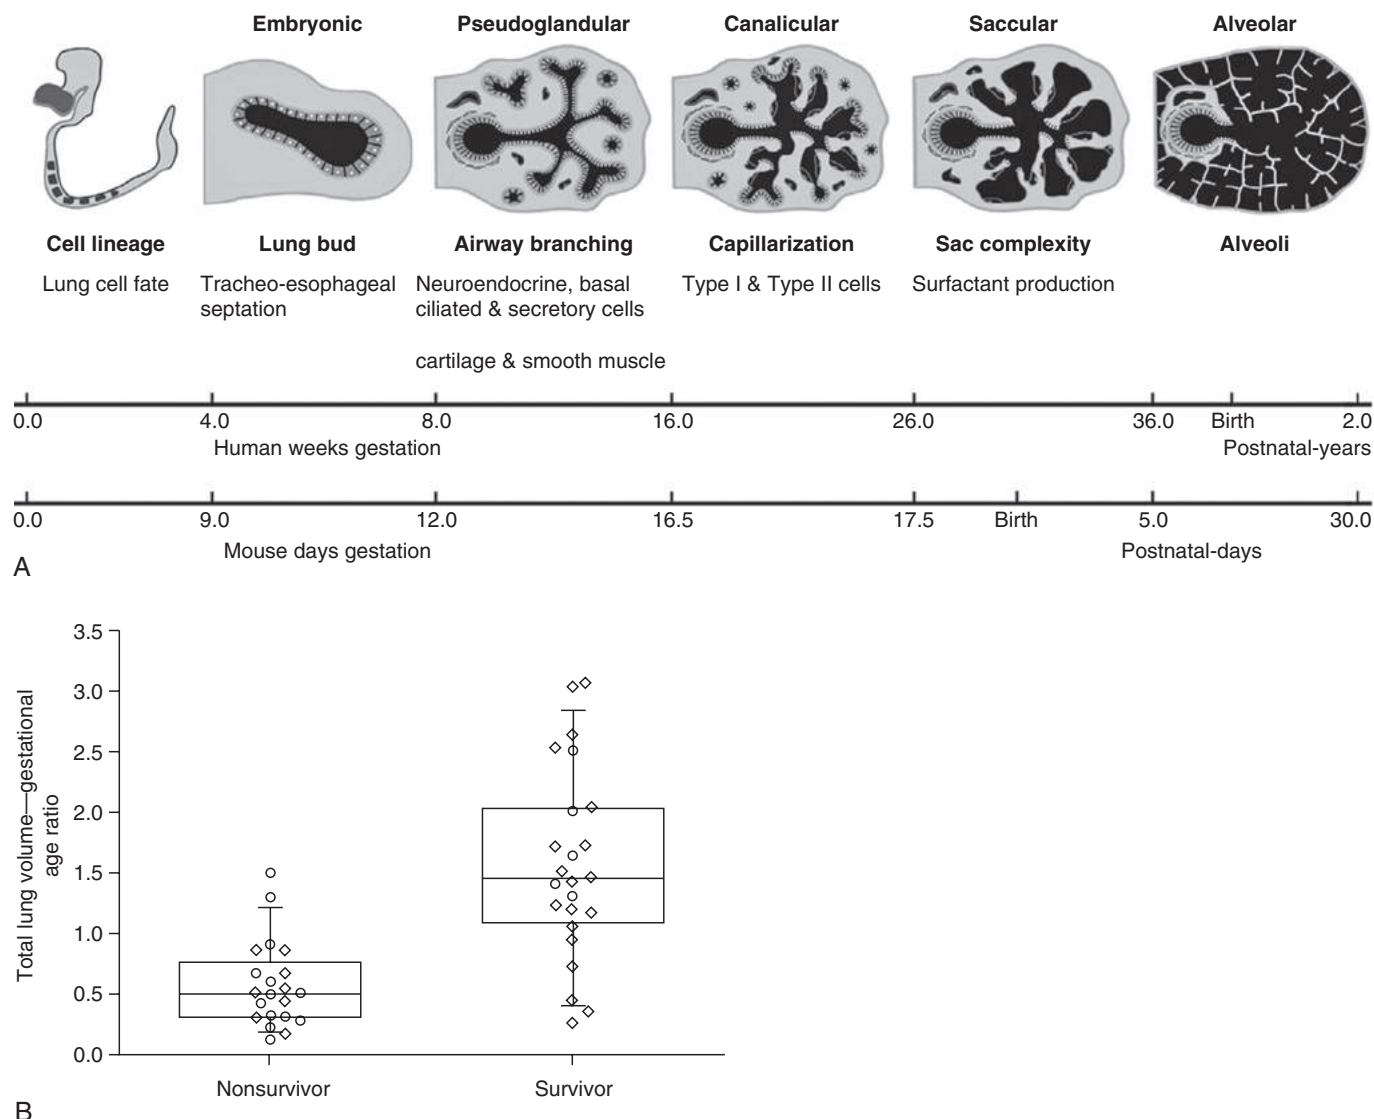

The preterm newborn with pulmonary hypoplasia often has immediate signs of respiratory distress and cyanosis indistinguishable from those in the newborn with severe RDS (see [Clinical Signs of Respiratory Distress Syndrome](#) earlier in this chapter). However, respiratory failure from severe pulmonary hypoplasia often becomes apparent within minutes of birth, whereas respiratory failure from RDS usually progresses over the first few hours after birth. The thorax may appear small or bell shaped, and, if oligohydramnios was severe, there may be flattening of the face and deformation (such as contractures of the extremities). Hypercarbia may be severe on the earliest blood gas measurement, despite aggressive mechanical ventilation. The hypoxemia from surfactant deficiency and lung immaturity may be compounded by right-to-left shunting of deoxygenated blood due to pulmonary hypertension, leading to severe desaturation. If there is also a tension pneumothorax, there may be asymmetry of breath sounds or malposition of heart sounds, as well as decreased cardiac output from impaired venous return to the thorax.

Radiographic Signs

Because lung immaturity and surfactant deficiency accompany pulmonary hypoplasia, particularly in preterm infants, the lungs may be radiographically dense with air bronchograms, as with RDS, but the lung volumes may be smaller and the diaphragms higher than in RDS. With severe pulmonary hypoplasia, the thorax may appear bell shaped, and early pneumothorax is common.

Treatment

With careful management, the survival rate of infants born at less than 32 weeks' gestation after rupture of membranes before 24 weeks' gestation has been reported as greater than 75%

• **Fig. 46.12** (A) Stages of lung development. (B) Measurement of fetal lung volume by magnetic resonance imaging and outcomes after delivery. ([A] From Kimura J, Deutsch GH. Key mechanisms of early lung development. *Pediatr Dev Pathol.* 2007;10:335–347. [B] From Zaretsky M, Ramus R, McIntire D, Magee K, Twickler DM. MRI calculation of lung volumes to predict outcome in fetuses with genitourinary abnormalities. *Am J Radiol.* 2005;185:1328–1334.)

(Soylu et al., 2010) and 90% (Brumbaugh et al., 2014). In addition to all of the treatments described earlier for the preterm infant with RDS, the ventilator strategy must be tailored to smaller lungs that may have relatively normal compliance, high pulmonary vascular resistance, and sometimes cardiac dysfunction. In the initial hours after birth, the goal should be to avoid excessive intrathoracic pressure from lung overdistention, which may lead to catastrophic pneumothorax and which may also further aggravate pulmonary hypertension and right-sided heart afterload. The neonatal team should be prepared for urgent needle decompression of the chest and insertion of a chest tube. Permissive hypercapnia is appropriate, and high-frequency ventilation may be necessary for adequate ventilation and reduction of very high arterial PCO_2 levels.

Exogenous surfactant should be considered early because RDS may complicate the management of pulmonary hypoplasia in the preterm infant. To avoid adding hypoxic pulmonary vasoconstriction to the already high pulmonary vascular resistance, the predudal

arterial oxygen saturation should be kept at 92% or higher. Although acidosis may compound hypoxic pulmonary vasoconstriction, hypercapnia is usually well tolerated and will allow a less aggressive ventilator strategy. Routine paralysis in preterm infants is usually not needed and leads to third spacing of fluid; usually narcotics will suffice to manage discomfort. Spontaneous ventilation may be beneficial, and some infants with pulmonary hypoplasia have been managed with use of nasal CPAP (Welzing et al., 2011).

Because increasing ventilator support for persistent hypoxemia is usually counterproductive, efforts should instead be directed toward treatment of pulmonary hypertension, even though the component that is reversible may be small if pulmonary hypoplasia is severe. There are several small studies demonstrating the beneficial effects of inhaled nitric oxide in infants after preterm prolonged rupture of membranes (de Waal and Kluckow, 2015), and the effects on shunt can be followed with serial echocardiography. Other medications that have been used in term infants with

pulmonary hypertension, such as sildenafil and milrinone, may be helpful. Because systemic hypotension causes worse right-to-left shunting, pressors such as dopamine may be helpful, acknowledging that these medications may increase both systemic and pulmonary vascular pressures. For more detail, see the review by [de Waal \(2015\)](#), which includes a good description of cardiovascular support agents, mechanisms of action, and physiologic targets. Before the start of administration of agents such as inhaled nitric oxide that are intended to increase pulmonary blood flow, severe left ventricular systolic dysfunction with increased left atrial pressure should first be corrected to avoid pulmonary edema.

Extracorporeal membrane oxygenation may be appropriate for late-gestation preterm infants if the pulmonary hypoplasia, surfactant deficiency, and pulmonary hypertension are expected to abate within a few days. However, it is very difficult to select appropriate candidates with pulmonary hypoplasia for extracorporeal membrane oxygenation, and it is often unsuccessful with severe disease or if other major life-threatening malformations are present.

Prenatal Diagnosis

An accurate prenatal test for pulmonary hypoplasia is important because it may affect the obstetric management. It would be particularly helpful to be able to discriminate lethal from nonlethal pulmonary hypoplasia, especially early in gestation, when termination of the pregnancy may be an option. However, quantifying the degree of fetal pulmonary hypoplasia is challenging even for the pathologist who has access to the tissue. A systematic review and metaanalysis of imaging parameters for prediction of fatal pulmonary hypoplasia found all to be poor to mediocre ([van Teeffelen et al., 2012](#)).

Nonsurvivors with pulmonary hypoplasia due to fetal urinary anomalies were noted to have lower in utero lung volumes as determined by fetal magnetic resonance imaging (MRI), adjusted for gestational age ([Zaretsky et al., 2005](#)), but there was no clear separation between the survivors and nonsurvivors (see [Fig. 46.12B](#)). Furthermore, there was considerable overlap of the confidence intervals before 26 weeks' gestation, which limits the usefulness of MRI assessment of fetal volume for prenatal counseling. Although there will continue to be advances in fetal imaging to assess lung volume, it will likely remain difficult to differentiate lethal from nonlethal pulmonary hypoplasia.

The management of the preterm pregnancy with premature rupture of membranes near the limit of fetal viability is beyond the scope of this chapter. However, a review by [Waters and Mercer \(2009\)](#) offers a management algorithm that illustrates the areas of controversy. For the patient who desires conservative management of premature rupture before the limit of viability, the algorithm recommends serial assessments for signs of infection or labor, as well as interval ultrasound examinations to watch for the development of pulmonary hypoplasia. If this occurs, prenatal administration of antibiotics and corticosteroids should be considered if more aggressive management is desired.

Prenatal Treatment

Treatment of oligohydramnios with amnioinfusion with saline has been proposed to improve fetal survival by increasing the latency period (the interval between premature rupture of membranes and delivery) and thus the gestational age at delivery. A metaanalysis found a reduction in neonatal morbidity, neonatal sepsis, pulmonary hypoplasia, puerperal sepsis, and latency, but

the authors recommended circumspection as the positive findings were mainly due to one trial with unclear allocation concealment ([Hofmeyr et al., 2014](#)). When it is successful, the benefit may come from restoration of back-pressure from the amniotic sac fluid to the lungs, stimulating fetal lung growth and development during the critical canalicular stage between 16 and 26 weeks' gestation.

On the basis of this same logic, there have been efforts to reverse pulmonary hypoplasia in utero by fetal tracheal occlusion with a balloon early in pregnancy. Recent research with this technique appears to be limited to fetuses with congenital diaphragmatic hernia ([Doné, 2015](#)). Whether this technique proves to be valuable for preterm premature rupture of membranes is uncertain, but pulmonary hypoplasia may be more reversible than previously assumed.

Pneumonia

Incidence and Etiology

The incidence of pneumonia and sepsis in infants with birth weight from 1500 to 2500 g is only 0.28%, whereas in patients with birth weight less than 1000 g the incidence is severalfold higher at 1.9% (see [Fig. 46.1](#); [Rubaltelli et al., 1998](#)). If only newborns with respiratory distress are considered, the overall incidence is 5% ([Table 46.1](#))—respiratory distress being the third most likely cause, after RDS (46%) and TTNB (37%). The incidence of pneumonia in newborns with respiratory distress who weigh less than 1000 g, 1000 to 1500 g, and 1500 to 2500 g is 4%, 2%, and 1%, respectively (see [Fig. 46.1](#)). The National Institute of Child Health and Human Development Neonatal Research Network reported an incidence of blood culture–proven early-onset sepsis (<72 hours after birth) in newborns with birth weight less than 1500 g of 1.9% in 1991 to 1993 ([Stoll et al., 1996](#)) and 1.5% in 1998 to 2000 ([Stoll and Hansen, 2003](#)). In the earlier period, group B streptococcus was the most frequent pathogen (31%), followed by *Escherichia coli* (16%) and *Haemophilus influenzae* (12%). In the more recent period, the most common pathogens were *E. coli* (44%), group B streptococcus (11%), coagulase-negative staphylococcus (11%), viridans streptococci and other streptococci (8%), *H. influenzae* (8%), *Citrobacter* (2%), *Listeria monocytogenes* (2%), and *Candida albicans* (2%). Preterm newborns can also acquire postnatal pertussis and viral pneumonia, commonly due to respiratory syncytial virus, adenovirus, and rhinovirus. Pneumonia can also begin in utero with infectious agents such as cytomegalovirus and herpes simplex virus (see Chapter 37).

Clinical Signs

The clinical signs of pneumonia after preterm birth are often indistinguishable from the more common problem of RDS. Bacterial pneumonia is usually accompanied by bacteremia because newborns are frequently unable to confine bacteria to the lung, and therefore some infants will exhibit clinical signs of sepsis or shock, including poor perfusion and hypotension, in addition to respiratory failure. Many premature infants with pneumonia also have surfactant deficiency from RDS, further obscuring the diagnosis of pneumonia.

Laboratory and Radiographic Signs

Blood culture findings will be positive in some premature newborns with pneumonia, but the presence of maternal antibiotics in the

blood of the newborn reduces confidence in a negative result. Leukopenia, increased percentage of immature granulocytes, and elevated levels of inflammatory markers such as C-reactive protein increase the likelihood of sepsis/pneumonia, but with poor positive predictive value. Tracheal aspirate culture (but not Gram stain) obtained immediately after placement of an endotracheal tube may help with diagnosis and guide therapy, especially when the blood culture result is negative (Booth et al., 2009).

Premature newborns with pneumonia will have pulmonary infiltrates on chest radiograph, but the radiographic appearance is difficult to distinguish from RDS (although classically in term newborns it has a more coarse and wetter appearance). Because newborns are unable to localize pulmonary infection, lobar infiltrates are rarely an indication of pneumonia—plugging of airways with secretions is more likely.

Treatment

Administration of antibiotics directed at the most common organisms (see earlier discussion) should be started immediately when pneumonia in the preterm infant is suspected. Ampicillin and gentamicin are reasonable choices, to be administered for 48 hours pending culture results. Empiric vancomycin has the disadvantage of promoting the emergence of vancomycin-resistant organisms, and a delay in treating coagulase-negative staphylococcal bacteremia until culture results are positive is rarely of consequence to the patient. If the blood culture result is negative, and the mother has been pretreated with antibiotics, a longer course of antibiotics (e.g., 5 to 7 days) may be prudent if the clinical course is strongly suggestive of pneumonia.

Among the possible adverse consequences of unnecessary empiric antibiotics are interference with the colonization of the intestinal tract with nonpathogenic bacteria, selection of antibiotic-resistant bacteria, and fungal infection. Although the development of BPD is associated with inflammation from chorioamnionitis (Speer, 2009), there is no convincing evidence that empiric antibiotics at birth reduce the incidence or severity of BPD.

Pulmonary Hemorrhage

Incidence and Clinical Signs

Pulmonary hemorrhage occurs in 3%–5% of preterm infants needing respiratory support, usually at 1 to 3 days of age, with onset of pink or red frothy fluids in the endotracheal tube and sudden respiratory deterioration, cyanosis, pallor, hypotension, or hypotonia (Bendapudi et al., 2012). The frequency is greater with increasing degree of prematurity and with intrauterine growth restriction (Scholl and Yanowitz, 2015). The chest radiograph shows widespread “whiteout” on chest radiograph, unlike mucosal bleeding of the airway, which is usually accompanied by minimal clinical or radiographic changes. The hematocrit of the tracheal fluid after pulmonary hemorrhage is much lower than from a venous sample, indicating that the underlying problem is hemorrhagic pulmonary edema.

Etiology

Pulmonary hemorrhage has long been speculated to be due to left ventricular failure and excessive left-to-right flow through a patent ductus arteriosus, with resultant disruption of the pulmonary capillaries (Cole et al., 1973). There is a threefold increased risk

after prophylactic synthetic surfactant (Soll, 2000), so some have speculated that it may have a direct cytotoxic effect that leads to impaired membrane integrity in the alveolar capillary (Findlay et al., 1995). However, it may be caused by insufficient attention to reducing mechanical ventilator pressure and volume after lung compliance improves following exogenous surfactant treatment. A recent case–control analysis (Scholl and Yanowitz, 2015) found a higher incidence of pulmonary hemorrhage in premature newborns with moderate-to-large patent ductus arteriosus who were extubated earlier than case-matched controls; the authors theorized that the decrease in pulmonary resistance associated with relief of RDS, combined with the reduction of mean airway support associated with extubation, facilitated left-to-right shunting through the patent ductus arteriosus, which increased the likelihood of pulmonary hemorrhage. This theory is supported by evidence that infants who received early indomethacin therapy to close a large patent ductus arteriosus had a lower incidence of pulmonary hemorrhage (Kluckow et al., 2014).

Treatment

The mainstay of treatment includes careful suctioning of the trachea to prevent obstruction, increased ventilator pressure if needed, and increased positive end-expiratory pressure for pulmonary edema. Although a low platelet count and coagulopathy are rarely the cause, newborns should be checked for these and treated if necessary. If anemia is severe, transfusion with packed red blood cells may be indicated, but this should be done very slowly to avoid compounding the pulmonary edema. In one small study, the trachea was “sprayed” with 0.5 mL of 1:10,000 epinephrine mixed with 1 mL of air in a 5-mL syringe through a small tube, after each suctioning of the endotracheal tube; most patients had resolution of pulmonary hemorrhage after three to five such treatments (Yen et al., 2013). Hemocoagulase, a purified enzyme mixture from the venom of the South American viper, has been used for its procoagulant effects in a small study of neonatal pulmonary hemorrhage, with a 48% reduction in mortality (Shi et al., 2005). Because red blood cells and serum impair surfactant function, there is evidence that exogenous surfactant helps (Pandit et al., 1995; Amizuka et al., 2003), but there are no randomized controlled trials to prove benefit (Aziz and Ohlsson, 2012).

Respiratory Disorders in the Term Infant

THOMAS A. PARKER AND JOHN P. KINSELLA

KEY POINTS

- Marked hypoxemia in the newborn can be caused by parenchymal lung disease, pulmonary vascular disease, or congenital heart defects.
- Events occurring at delivery, as well as the response to supplemental oxygen and to mask continuous positive airway pressure, can provide important clues to the pathophysiology of hypoxemic respiratory failure in the term newborn.
- Although a significant percentage of term births are complicated by passage of meconium in utero, less than 10% of such infants develop meconium aspiration syndrome.
- Transient tachypnea of the newborn is one of the most common causes of respiratory distress in the term newborn.
- The most important question to ask when one is reviewing a neonatal chest X-ray is whether the severity of hypoxemia is out of proportion to the X-ray findings.
- The syndrome of persistent pulmonary hypertension of the newborn rarely occurs without concomitant parenchymal lung disease.
- The echocardiogram has become a vital tool in the clinical management of newborns with hypoxemic respiratory failure, including the diagnosis of congenital heart defects for which inhaled nitric oxide treatment would be contraindicated.

The evaluation and management of respiratory distress in the term newborn poses unique challenges and remains one of the most vexing problems facing neonatal caregivers. Although some of the pathophysiologic features of respiratory disorders in the term infant are similar to those in preterm newborns, several disorders occur more commonly in the term newborn (e.g., meconium aspiration) and are often made more difficult to evaluate and manage because of cardiac and pulmonary vascular abnormalities that complicate the clinical course. Indeed, the traditional perspective of categorizing hypoxemia and respiratory failure in the term newborn as due to cardiac, pulmonary vascular, or air space (lung) disease is insufficient. For example, the problem of persistent pulmonary hypertension of the newborn (PPHN) is defined by severe pulmonary vasoconstriction leading to suprasystemic pulmonary artery pressure with extrapulmonary right-to-left venoarterial admixture across the fetal channels of the oval foramen and the arterial duct. However, PPHN rarely occurs without concomitant parenchymal lung disease and disturbances in cardiac performance.

In this chapter we present an algorithm for evaluation of the term newborn with hypoxemia and respiratory distress, review the syndrome of PPHN, and discuss common causes of respiratory failure in the term newborn.

Evaluation of the Term Newborn With Hypoxemia/Respiratory Distress

One of the most anxiety-provoking experiences for many clinicians (particularly those in training) is the initial evaluation and management of a term newborn with hypoxemia and respiratory distress. Traditional textbooks provide a wealth of information about individual conditions once they have been identified. However, there are few sources designed to guide the clinician in an ordered fashion through a comprehensive diagnostic evaluation. In this section, we propose an approach to the evaluation of the hypoxemic newborn that may be useful in clarifying the cause of hypoxemia/respiratory distress and in determining the proper sequence of diagnostic and therapeutic interventions.

History

Marked hypoxemia in the newborn can be caused by parenchymal lung disease with ventilation-perfusion (V/Q) mismatch or intrapulmonary shunting, pulmonary vascular disease causing extrapulmonary right-to-left shunting (PPHN), or anatomic right-to-left shunting associated with congenital heart disease. Evaluation should begin with a history that includes assessment of risk factors for hypoxemic respiratory failure. A relevant history may include the results of prenatal ultrasound studies. Lesions such as congenital diaphragmatic hernia (CDH) and congenital cystic adenomatoid malformation are diagnosed prenatally with increasing frequency. Although many anatomic congenital heart defects can be diagnosed prenatally, vascular abnormalities (e.g., coarctation of the aorta, total anomalous pulmonary venous return) are more difficult to diagnose with prenatal ultrasonography. A history of a structurally normal heart by fetal ultrasonography should be confirmed by echocardiography in the newborn with cyanosis (see later).

Other historical information that may be important in the evaluation of the cyanotic newborn includes a history of severe and prolonged oligohydramnios causing pulmonary hypoplasia. Also important is a history of prolonged fetal bradyarrhythmia

• BOX 47.1 Neonatal Respiratory Failure: History and Risk Factor Assessment

Prenatal

Prenatal ultrasound study results
History of oligohydramnios and duration
History of fetal brady/tachyarrhythmia
Maternal illnesses, drugs, medications
History of fetal distress
Risk factors for infection

Delivery

History of positive pressure ventilation in delivery room
Meconium-stained amniotic fluid
Hemorrhage
Birth trauma
Low Apgar score

and/or tachyarrhythmia and marked anemia (caused by hemolysis, twin–twin transfusion, or chronic hemorrhage) that may cause congestive heart failure, pulmonary edema, and respiratory distress. Maternal illness (e.g., diabetes mellitus), medication use (e.g., aspirin or medications containing nonsteroidal antiinflammatory drugs causing premature constriction of the ductus arteriosus, association of Ebstein malformation with maternal lithium use), and illicit drug use may contribute to acute cardiopulmonary distress in the newborn. Risk factors for infection that cause sepsis/pneumonia should be considered, including premature or prolonged rupture of membranes, fetal tachycardia, maternal leukocytosis, uterine tenderness, and other signs of intra-amniotic infection.

Events at delivery may provide clues to the cause of hypoxemic respiratory failure in the newborn. For example, if positive pressure ventilation is required in the delivery room, the risk of pneumothorax increases. A history of meconium-stained amniotic fluid is the sine qua non of meconium aspiration syndrome (MAS). Birth trauma (e.g., clavicular fracture, phrenic nerve injury) or acute fetomaternal or fetoplacental hemorrhage may cause respiratory distress in the newborn (Box 47.1).

Physical Examination

The initial physical examination provides important clues to the cause of cyanosis. Marked respiratory distress in the newborn (retractions, grunting, nasal flaring) suggests the presence of pulmonary parenchymal disease with decreased lung compliance. However, it is important to recognize that upper airway obstruction (e.g., Pierre Robin sequence or choanal atresia) and metabolic acidemia also can cause severe respiratory distress. In contrast, the newborn with cyanosis alone or cyanosis plus tachypnea (i.e., nondistressed tachypnea) typically has cyanotic congenital heart disease, most commonly transposition of the great vessels or idiopathic PPHN.

The presence of a heart murmur in the first few hours of life is an important sign in the newborn with cyanosis or respiratory distress. In this setting it is unusual for the common left-to-right shunt lesions (patent ductus arteriosus, atrial septal defect, ventricular septal defect) to produce an audible murmur because pulmonary vascular resistance (PVR) remains high and little turbulence is created across the defect. A murmur that sounds like a ventricular septal defect in the first few hours of life is most commonly caused by tricuspid regurgitation (associated with PPHN or an ischemic myocardium).

• BOX 47.2 Physical Examination

Respiratory Distress (Retractions, Grunting, Nasal Flaring)

Suggests lung parenchymal disease (compliance), upper airway disease, or metabolic acidemia

No Significant Respiratory Distress (Tachypnea Alone)

Suggests hypoxemia caused by cyanotic heart disease without lung disease

• BOX 47.3 Short-Term Response to Supplemental Oxygen (High FiO_2 by Hood, Mask)

Minimal or Transient Change in SaO_2

Cyanotic heart disease, persistent pulmonary hypertension of the newborn

Marked increase in SaO_2

Parenchymal lung disease, congenital diaphragmatic hernia with ductal-dependent systemic blood flow

FiO_2 , Fraction of inspired oxygen; SaO_2 , Arterial oxygen saturation.

The response to supplemental oxygen can also provide important clues to the pathophysiology of hypoxemic respiratory failure in the term newborn (Boxes 47.2–47.3).

Interpretation of Pulse Oximetry Measurements

The interpretation of preductal (right hand) and postductal (lower extremity) arterial oxygen saturation, measured by pulse oximetry, provides important clues to the cause of hypoxemia in the newborn. Right-to-left shunting across the ductus arteriosus (but not the patent foramen ovale) causes postductal desaturation (with a >5% preductal–postductal saturation difference). However, it is important to recognize that variability in oximetry readings may be related to differences in available devices and may be affected by local perfusion.

If the measurements of preductal and postductal arterial oxygen saturation (SaO_2) are equivalent, this suggests either that the ductus arteriosus is patent and PVR is subsystemic (i.e., the hypoxemia is caused by parenchymal lung disease with intrapulmonary shunting or cyanotic heart disease with ductal-dependent pulmonary blood flow) or that the ductus arteriosus is closed (precluding any interpretation of pulmonary artery pressure without echocardiography). It is uncommon for the ductus arteriosus to close in the first few hours of life in the presence of systemic or suprasystemic pulmonary artery pressures.

The most common cause of preductal–postductal gradients in oxygenation is suprasystemic PVR in PPHN causing right-to-left shunting across the ductus arteriosus (associated with MAS, surfactant deficiency/dysfunction, CDH, non-CDH pulmonary hypoplasia, or idiopathic [pulmonary hypertension without accompanying pulmonary parenchymal disease]). However, ductal-dependent systemic blood flow lesions (hypoplastic left-sided heart syndrome, critical aortic stenosis, interrupted aortic arch, coarctation) may also present with postductal desaturation. Moreover, anatomic pulmonary vascular disease (alveolar capillary dysplasia, pulmonary venous stenosis, anomalous venous return with obstruction) can cause suprasystemic PVR with right-to-left shunting across the ductus arteriosus and postductal desaturation.

TABLE 47.1 Role of Pulse Oximetry in Evaluation of Neonatal Hypoxemic Respiratory Failure

| | |
|--|---|
| Preductal $\text{SaO}_2 =$ postductal SaO_2 | Intrapulmonary shunt: $\text{PVR} < \text{SVR}$ Cyanotic congenital heart disease with left-to-right shunting across the PDA Ductal-dependent pulmonary blood flow: pulmonary atresia/stenosis, tricuspid atresia, Ebstein anomaly PPHN: right-to-left shunt at PFO, $\text{PVR} > \text{SVR}$, ductus closed |
| Preductal $\text{SaO}_2 >$ postductal SaO_2 | $\text{PVR} > \text{SVR}$ with right-to-left shunting across the PDA: PPHN: MAS, RDS, CDH Ductal-dependent systemic blood flow: HLHS, IAA, coarctation Anatomic pulmonary vascular disease: alveolar capillary dysplasia, pulmonary vein stenosis, TAPVR with obstruction |
| Preductal $\text{SaO}_2 \leq$ postductal SaO_2 | TGV with pulmonary hypertension TGV with coarctation of the aorta |

CDH, Congenital diaphragmatic hernia; HLHS, hypoplastic left-sided heart syndrome; IAA, interrupted aortic arch; MAS, meconium aspiration syndrome; PDA, patent ductus arteriosus; PFO, patent foramen ovale; PPHN, persistent pulmonary hypertension of the newborn; PVR, pulmonary vascular resistance; RDS, respiratory distress syndrome; SaO_2 , arterial oxygen saturation; SVR, systemic vascular resistance; TAPVR, total anomalous pulmonary venous return; TGV, transposition of the great vessels.

Finally, the unusual occurrence of markedly lower preductal SaO_2 compared with postductal SaO_2 suggests one of two diagnoses: transposition of the great vessels (TGV) with pulmonary hypertension (PH) or TGV with coarctation of the aorta (Table 47.1).

Laboratory and Radiologic Evaluation

One of the most important tests to perform in the evaluation of the newborn with cyanosis is the chest radiograph (CXR). The CXR can demonstrate the classic findings of respiratory distress syndrome (RDS) (air bronchograms, diffuse granularity, underinflation), pneumonia (diffuse parenchymal lung disease), MAS, or CDH. Perhaps the most important question to ask when one is viewing the CXR is whether the severity of hypoxemia is out of proportion to the radiographic changes. In other words, marked hypoxemia despite supplemental oxygen in the absence of severe pulmonary parenchymal disease radiographically suggests the presence of an extrapulmonary right-to-left shunt (idiopathic PPHN or cyanotic heart disease; Boxes 47.3–47.4).

Other essential measurements include measurement of arterial blood gas to determine the blood gas tensions and pH, a complete blood count to evaluate the newborn for signs of infection, and blood pressure measurements in the right arm and a lower extremity to identify aortic obstruction (interrupted aortic arch, coarctation).

Response to Supplemental Oxygen

A marked increase in SaO_2 (increase to 100%) with supplemental oxygen (by hood, mask, or endotracheal tube) suggests the presence of intrapulmonary shunt or V/Q mismatch caused by lung disease or reactive PPHN. The response to mask continuous positive airway pressure is also a useful discriminator between severe lung disease and other causes of hypoxemia. Most patients with PPHN have

• BOX 47.4 Chest Radiograph and Laboratory Evaluation

Chest Radiograph

Hypoxemia out of proportion to radiographic changes suggests congenital heart disease with ductal-dependent pulmonary blood flow or extrapulmonary right-to-left shunting with persistent pulmonary hypertension of the newborn.

Arterial Blood Gas, Complete Blood Count, Blood Pressure

Arterial blood gas: assess respiratory and metabolic acidemia

Complete blood count: for evidence of infection

Blood pressure: ductal-dependent systemic blood flow and closing of patent ductus arteriosus (e.g., coarctation)

• BOX 47.5 Role of Echocardiography in Evaluation of Persistent Pulmonary Hypertension of the Newborn and the Use of Inhaled Nitric Oxide

Extrapulmonary Shunt

Right-to-left shunting at the arterial duct and/or foramen ovale is observed in infants with suprasystemic pulmonary hypertension.

If echocardiography demonstrates adequate left-ventricular performance, consider inhaled NO use after effective lung recruitment (see functional measurements below).

Anatomy

Inhaled NO use may be contraindicated in the presence of duct-dependent systemic blood flow (e.g., hypoplastic left heart syndrome).

Left-Ventricular Performance

Inhaled NO use may be contraindicated in the presence of left ventricular systolic/diastolic dysfunction (e.g., mitral insufficiency with left-to-right atrial shunting with right-to-left ductal shunting suggesting possible right ventricle-dependent systemic blood flow).

NO, Nitric oxide.

at least a transient increase in oxygenation in response to interventions such as high inspired oxygen concentration and/or initiation of mechanical ventilation. If preductal SaO_2 never reaches 100%, the likelihood of cyanotic heart disease is high.

Echocardiography

Echocardiography has become a vital tool in the clinical management of newborns with hypoxemic respiratory failure (Box 47.5). The initial echocardiographic evaluation is important to rule out structural heart disease causing hypoxemia (e.g., coarctation of the aorta, total anomalous pulmonary venous return). Moreover, it is critically important to diagnose congenital heart lesions for which inhaled nitric oxide (iNO) treatment would be contraindicated. In addition to the lesions mentioned earlier, congenital heart diseases that can present with hypoxemia unresponsive to high inspired oxygen concentrations (i.e., dependent on right-to-left shunting across the ductus arteriosus) include critical aortic stenosis, interrupted aortic arch, and hypoplastic left-sided heart syndrome. Decreasing PVR with iNO treatment in these conditions could lead to systemic hypoperfusion, worsening the clinical course and delaying definitive diagnosis.

Echocardiographic evaluation is an essential component in the initial evaluation and ongoing management of the hypoxemic newborn. Not all hypoxemic term newborns have echocardiographic signs of PPHN. As noted earlier, hypoxemia can be caused by intrapulmonary right-to-left shunting or V/Q disturbances associated with severe lung disease. In unusual circumstances, right-to-left shunting can occur across pulmonary-to-systemic collaterals. However, extrapulmonary right-to-left shunting at the foramen ovale and/or ductus arteriosus (PPHN) also complicates hypoxemic respiratory failure and must be assessed to determine initial treatments and evaluate the response to those therapies.

PPHN is defined by the echocardiographic determination of extrapulmonary venoarterial admixture (right-to-left shunting at the foramen ovale and/or ductus arteriosus), not simply evidence of increased PVR (i.e., elevated PVR without extrapulmonary shunting does not directly cause hypoxemia). Echocardiographic signs suggestive of PH (e.g., increased right ventricular systolic time intervals, septal flattening) are less helpful.

Doppler measurements of atrial-level and ductal-level shunts provide essential information when one is managing hypoxemic respiratory failure in a newborn. For example, left-to-right shunting at the foramen ovale and ductus arteriosus with marked hypoxemia suggests predominant intrapulmonary shunting, and interventions should be directed at optimizing lung inflation.

Finally, the measurements made with echocardiography can be used to predict or interpret the response or lack of response to various treatments. For example, in the presence of severe left-ventricular dysfunction with pulmonary hypertension, pulmonary vasodilation alone may be ineffective in increasing oxygenation. The echocardiographic findings in this setting include right-to-left ductal shunting (caused by suprasystemic PVR) and mitral insufficiency with left-to-right atrial shunting. In this setting, efforts to reduce PVR should be accompanied by targeted therapies to increase cardiac performance and decrease left-ventricular afterload.

This constellation of findings suggests that left-ventricular dysfunction may contribute to pulmonary venous hypertension, such as occurs in congestive heart failure. In this setting, pulmonary vasodilation alone (without improvement in cardiac performance) will not cause a sustained increase in oxygenation. Careful echocardiographic assessment will provide invaluable information about the underlying pathophysiology and help guide the course of treatment.

The initial echocardiographic evaluation determines both structural and functional (i.e., extrapulmonary right-to-left shunting in PPHN, left-ventricular performance) causes of hypoxemia. Serial echocardiography is important to determine the response to interventions (e.g., pulmonary vasodilators) and to reevaluate cases where specific interventions have not resulted in improvement or with progressive clinical deterioration. For example, in a patient with extrapulmonary right-to-left shunting and severe lung disease, pulmonary vasodilation might reverse the right-to-left venous admixture with little increase in systemic oxygenation. These observations unmask the critically important contribution of intrapulmonary shunting to hypoxemia.

Persistent Pulmonary Hypertension of the Newborn

As described previously, PPHN is a syndrome associated with diverse neonatal cardiac and pulmonary disorders that are characterized by high PVR causing extrapulmonary right-to-left shunting of blood

across the ductus arteriosus and/or foramen ovale. The syndrome of PPHN and the role of iNO are discussed in more detail in Chapter 52. However, because its relationship to respiratory failure in term newborns is so vital to understanding the clinical pathophysiology and approaches to treatment, we briefly address some historical perspectives in this section. Indeed, to understand the acronym PPHN, it is important to consider its historical evolution in term newborns with respiratory failure and critical hypoxemia and the advances that led to current management strategies.

In the early 1960s the association of RDS with PH and right-to-left ductal shunting was described in the landmark studies of [Rudolph et al. \(1961\)](#) and the clinical observations of [Stahlman \(1964\)](#). The first clear description of the pathophysiology of PPHN is attributed to [Gersony et al. \(1969\)](#), who coined the phrase *persistence of the fetal circulation* (PFC) in describing two newborns with clear lung fields who had critical hypoxemia associated with severe PH and right-to-left shunting across the foramen ovale and ductus arteriosus. In the next decade, several authors reported small series of infants with physiology similar to that described by Stahlman and Gersony et al. ([Lees, 1970](#); [Siassi et al., 1971](#); [Haworth and Reid, 1976](#)). The phrase *persistent pulmonary hypertension of the newborn* was first used by [Levin et al. \(1976\)](#) to describe a group of newborns with severe pulmonary hypertension, clear CXRs, and right-to-left shunting across the ductus arteriosus demonstrated both by simultaneous temporal arterial and umbilical arterial sampling (i.e., postductal desaturation) and by cardiac catheterization.

These initial descriptions of PFC focused on a discreet subset of newborns who had adequate cardiac performance without structural heart disease, absence of significant parenchymal lung disease, and suprasystemic PVR causing hypoxemia through right-to-left shunting of blood across the oval foramen and/or the arterial duct. However, it soon became clear that PFC could complicate the course of other diseases of the newborn, particularly meconium aspiration—initially described by [Stahlman \(1964\)](#) and later by [Fox et al. \(1977\)](#)—and pulmonary hypoplasia/CDH ([Harrison and de Lorimier, 1981](#)).

The nomenclature for this syndrome was clearly quite varied. Although there was initial appeal of the term *persistent fetal circulation* ([Behrman, 1976](#)), this description is not quite accurate because of the absence of the placenta and onset of air breathing after delivery. Over time, most authors have embraced *persistent pulmonary hypertension of the newborn* or PPHN as the proper name for this syndrome, with the classic PFC subtype (idiopathic PPHN) representing a relatively small percentage of the cases now commonly encountered. Pathophysiologic mechanisms and etiologic classifications of PPHN described by [Rudolph \(1980\)](#) and further characterized by [Geggel and Reid \(1984\)](#) and [Gersony \(1984\)](#) provided an important framework for understanding the complex nature of this syndrome as management strategies evolved over the past 2 decades.

Because of the role of PH in newborns with hypoxemic respiratory failure (initially severe hyaline membrane disease [HMD] and subsequently PFC, as described earlier), early approaches to management included a focus on pulmonary vasodilation using tolazoline, one of the few pharmacologic agents available at the time. Its use was first described by [Cotton \(1965\)](#) in newborns with HMD and later in infants with PPHN by [Gersony et al. \(1969\)](#), [Korones and Eyal \(1975\)](#), and [Levin et al. \(1976\)](#). However, its efficacy was limited by variable responsiveness and significant complications, including systemic hypotension and gastrointestinal hemorrhage ([Goetzman et al., 1976](#); [Stevenson et al., 1979](#)).

Multiple approaches to the treatment of PPHN evolved after its first recognition as a disease marked by severe pulmonary hypertension, but therapy was limited by the lack of suitable selective pulmonary vasodilators. Intensive investigation ultimately led to the discovery of nitric oxide (NO) as the endothelium-derived relaxing factor responsible for the rapid decline in PVR at birth (Abman, 1990). This recognition finally provided investigators with a selective vasodilator that has led to striking changes in the management of PPHN in the past 20 years.

The observation that dilute NO gas could be therapeutically delivered by inhalation was first described by Pepke-Zaba, who reported that brief iNO treatment caused potent and selective pulmonary vasodilation in adults with severe PH (Pepke-Zaba et al., 1991). Frostell et al. (1991) demonstrated the selectivity of iNO in an adult animal model of hypoxic pulmonary vasoconstriction, and the first description of the potent, sustained, and selective vasodilator effect of iNO in newborn lambs was reported by Kinsella et al. (1992). The current use of iNO and other approaches to PPHN treatment as they relate to specific respiratory diseases are discussed in the following sections.

Specific Pulmonary Conditions Causing Respiratory Distress in the Term Newborn

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTNB) is among the most common causes of respiratory distress in the newborn period, affecting 0.5%–4% of all late preterm and term neonates. The symptoms of respiratory distress typically start within the first several hours after birth and result from failure of adequate absorption of fetal lung fluid. Studies have consistently shown that risk factors for TTNB include prematurity, birth by cesarean delivery, and male sex (Riskin et al., 2005; Jain et al., 2009; Silasi et al., 2010). Among babies born by elective cesarean delivery, a recent study suggests that delivery before 39 weeks increases the risk of TTNB by more than twofold (Doan et al., 2014).

Early theories of lung fluid clearance focused on the role of thoracic compression during vaginal delivery and were supported by the observation that TTNB is more common among babies born by cesarean delivery (Milner et al., 1978). However, more recent studies have demonstrated that the complex process of lung liquid clearance likely begins well before term birth (Brown et al., 1983). During fetal life the lung epithelium is responsible for the production of a substantial volume of alveolar fluid, a process that is essential for normal fetal lung growth (Olver and Strang, 1974). With parturition, increased levels of epinephrine, glucocorticoids, and other hormones effectively cause the lung epithelia to transition from a secretory to a resorptive phenotype (Barker et al., 1990; Baines et al., 2000). Activated endothelial sodium channels (ENaC) at the apical surface of lung type II epithelial cells transport sodium and water from the alveolar space into the type II cells (Olver et al., 1986). Sodium is then actively moved from the type II cell into the interstitium by sodium-potassium pump (Na/K-ATPase), causing passive movement of water, which is then resorbed into the pulmonary circulation and lymphatics. Supporting a possible role for abnormal activity of ENaC and Na/K-ATPase in TTNB, it has been found that genetic polymorphisms in β -adrenergic receptor–encoding genes (which regulate expression of these channels) are more common in babies with TTNB (Aslan et al., 2008).

The diagnosis of TTNB remains problematic for clinicians. The most typical presenting symptoms, tachypnea/respiratory distress and the need for supplemental oxygen, are common among most neonatal respiratory disorders, and unfortunately, there exist no reliable diagnostic tests for TTNB (Guglani et al., 2008). For those reasons the diagnosis remains one of exclusion, and vigilance for other, more severe disorders is imperative. Typically, symptoms of TTNB develop within the first several hours after birth. The degree of respiratory impairment, including the respiratory rate, use of accessory respiratory muscles, and impairment in gas exchange, differs widely. CXRs should be considered in any baby presumed to have TTNB. Although radiographs commonly show prominent perihilar markings and fluid in the fissures, clinicians and radiologists often disagree in their interpretation of these findings in TTNB (Kurl et al., 1997).

Once a presumptive diagnosis of TTNB has been made, treatment is largely supportive. Oxygen should be provided to maintain normal arterial oxygen saturations. The degree of tachypnea and respiratory distress should determine whether a baby is allowed to feed by mouth. If there is a suspicion of pneumonia or sepsis, empiric antibiotic therapy should be considered. A controlled trial of furosemide administration to accelerate clearance of lung fluid showed no benefit in attenuating the course of TTNB (Wiswell et al., 1985). A prospective study suggests that moderate fluid restriction for the first 72 hours reduced the duration of respiratory support and cost of hospitalization (Stroustrup et al., 2012). Alternative or additional diagnoses should be considered in any infant who is deteriorating or requires mechanical ventilation. With supportive care, full recovery is to be expected after TTNB. However, compared with well infants of a similar gestational age, newborns with TTNB have a significantly prolonged hospital course (Riskin et al., 2005). Moreover, recent epidemiologic studies have suggested that newborns with TTNB are at a mildly increased risk of the later development of asthma (Birnkranz et al., 1996; Schaubel et al., 2006; Liem et al., 2007).

Meconium Aspiration Syndrome

MAS is associated with inhalation of meconium and amniotic fluid during fetal life or at delivery and is often complicated by significant pulmonary hypertension. It is among the most common causes of hypoxemic respiratory failure in term newborns who require intensive care (Fig. 47.1). The incidence of MAS in babies born after 37 weeks' gestation ranges from 0.4% to 1.8% (Dargaville and Copnell, 2006; Singh et al., 2009), and a study suggests that the rate of MAS may have been declining in recent years (Vivian-Taylor et al., 2011). Among babies born after 39 weeks' gestation with lung disease requiring mechanical ventilation, more than half have MAS (Gouyon et al., 2007). Moreover, MAS is the primary diagnosis for a significant proportion of those newborns who require extracorporeal membrane oxygenation (ECMO) in the United States (26%) and the United Kingdom (51%) (Brown et al., 2010).

Although a significant percentage of term births are complicated by the passage of meconium before or at delivery, less than 10% of those exposed to meconium develop MAS. Among that 10%, fetal acidemia is believed to cause increased intestinal peristaltic activity that results in passage of meconium and fetal gasping, which draws meconium-contaminated amniotic fluid deep into the lungs. Supporting this theory, autopsy studies of babies who died of MAS demonstrate distal muscularization of small pulmonary arterioles, suggesting long-standing hypoxemia (Murphy et al., 1984). Recent work suggests that activation of inflammatory cascades

• **Fig 47.1** Chest radiograph of term newborn with severe meconium aspiration syndrome. Note the anterior pneumomediastinum and small left anteromedial pneumothorax.

may worsen the severity of MAS (Lindenskov et al., 2015; Lee et al., 2016). Particulate meconium in the distal airways causes check-valve obstruction of air passages and leads to regional hyperinflation and atelectasis. In addition, meconium inactivates surfactant, leading to secondary surfactant deficiency (Moses et al., 1991). Moreover, babies with MAS are at high risk of persistent pulmonary hypertension, which significantly increases their morbidity and complicates their management.

Historically, prevention of MAS has focused on decreasing exposure of the fetal and newborn lung to the noxious effects of intrapulmonary meconium-contaminated amniotic fluid. Infusion of saline into the amniotic cavity (i.e., amnioinfusion) during labor has been studied as a means of both diluting meconium and relieving pressure on the umbilical cord, a potential cause of fetal acidemia. In the largest trial investigating this practice, Fraser et al. (2005) found no reduction in the risk of MAS. An alternative strategy for decreasing lung exposure to meconium is intrapartum oropharyngeal and nasopharyngeal suction of fetuses born through meconium-stained amniotic fluid. Although this practice was widely adopted in the 1970s, more recent studies have failed to demonstrate benefit (Vain et al., 2004), and the practice is no longer endorsed by the American College of Obstetricians and Gynecologists (Committee on Obstetric Practice, American College of Obstetricians and Gynecologists, 2007). Moreover, the current American Academy of Pediatrics/American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care of the neonate no longer recommend intubation and tracheal suctioning for nonvigorous newborns born through meconium-stained amniotic fluid (Wyckoff et al., 2015).

The clinical signs of MAS differ widely among babies and may relate to the degree of prenatal compromise, the timing, volume, and consistency of aspirated meconium, and the presence of associated problems. Clinical signs of MAS typically present immediately after birth with tachypnea, increased work of breathing, and cyanosis. Other common associated findings include metabolic acidosis, cardiac dysfunction and hypotension, and postductal desaturation indicative of right-to-left shunting of blood at the ductus arteriosus caused by pulmonary hypertension. Because of the potential for ball-valve obstruction of small airways and failure to empty distal lung segments, pneumothorax can complicate the

clinical picture. In recent series, the risk of pneumothorax among ventilated babies with MAS ranged between 10% and 24% (Dargaville and Copnell, 2006; Velaphi and Van Kwawegen, 2008). Like the degree of clinical signs, CXR findings differ widely. The classic CXR shows diffuse, fluffy infiltrates. However, some babies have milder initial radiographic findings, and there is often progression of visible parenchymal disease over time, likely related to secondary surfactant dysfunction.

Approximately half of babies with MAS require mechanical ventilation. The ventilator strategy should be individualized to each baby and to the disease evident on the CXR. In general, because of the likelihood of increased airway resistance, a conventional strategy using slower rates with long inspiratory and expiratory times allows better gas dispersion and more adequate emptying during expiration. Gas trapping and regional or generalized hyperinflation can occur, particularly when rapid rates are used with a conventional mode of ventilation. Some babies respond better to ventilation with a high-frequency device, although there is also a high risk of hyperinflation. When severe, hyperinflation causes impaired gas exchange and hypercarbia, limits systemic venous return (adversely affecting cardiac performance), increases the risk of pneumothorax, and may exacerbate pulmonary hypertension. Surfactant lung lavage has demonstrated some promise in improving lung function in animal models of MAS (Dargaville et al., 2003), but a small clinical trial of this practice demonstrated no benefit (Gadzinowski et al., 2008). However, conventional surfactant administration in infants with MAS may reduce the severity of illness and decrease the need for treatment with ECMO (El Shahed, 2014). In addition to management of parenchymal lung disease in MAS, special consideration must be given to other associated problems, particularly pulmonary hypertension. The risk of PPHN is quite high, exceeding 50% in some series. It has been demonstrated that iNO treatment increases oxygenation in MAS and is particularly efficacious when combined with a ventilator strategy that focuses on improving lung recruitment such as high-frequency oscillatory ventilation (Kinsella et al., 1997). Treatment with antibiotics with systemic effect should also be strongly considered in babies with PPHN for a number of reasons. These include the fact that intrauterine infection might be a precipitating factor in the initial passage of meconium and that in vitro studies suggest that the presence of meconium might facilitate the growth of bacteria in the lung.

In spite of the availability of iNO treatment and high-frequency modes of ventilation, some babies do not respond to medical therapy and require treatment with ECMO. Among babies with MAS treated with ECMO, reported survival ranges between 94% and 97%, markedly higher than for newborns treated for other respiratory conditions (Gill et al., 2002; Brown et al., 2010).

Surfactant Protein Deficiency

The details of surfactant biology and of RDS in premature newborns are presented in Chapter 12. However, term newborns may rarely present with a clinical syndrome dominated by respiratory failure that may be indistinguishable from surfactant deficiency in preterm infants. In the setting of unexplained and protracted respiratory failure in term infants, genetic alterations of surfactant-associated proteins, particularly surfactant protein B (SP-B), surfactant protein C (SP-C), and adenosine triphosphate (ATP)-binding cassette subfamily A member 3 (ABCA3), must be considered and ruled out. In addition, defective signaling of granulocyte-macrophage colony-stimulating factor, which regulates alveolar macrophages

and surfactant catabolism, may cause progressive interstitial lung disease in infants (Whitsett et al., 2015).

As described later, there is considerable overlap in the clinical presentation of babies with mutations of SP-B, SP-C, and ABCA3. Although onset, severity of clinical signs, and a family history of lung disease may offer clues to the underlying disorder, a full histologic and genetic evaluation should be considered. Genetic analysis of blood or buccal swabs for mutations of the genes encoding SP-B, SP-C, and ABCA3 are the definitive tests for each disease, but analysis is both costly and time consuming. Moreover, analysis is not routinely available, necessitating transport of specimens to a small number of laboratories specializing in these analyses. In addition, bronchoalveolar lavage (BAL) aspirate should be analyzed by enzyme-linked immunosorbent assay for the presence of SP-B and pro-SP-C. Lung biopsy, perfused by both standard microscopy and electron microscopy, can also provide important clues to the underlying diagnosis.

Surfactant-Associated Protein B Deficiency

Mature SP-B is a small hydrophobic protein (79 amino acids) that plays several key roles in the processing and function of normal pulmonary surfactant (Nogee et al., 2000). Transgenic mouse models suggest that SP-B is critical for phospholipid packaging into lamellar bodies, the formation of tubular myelin, and spreading/function of the surfactant monolayer. In addition, normal SP-B appears to be essential for normal processing of SP-C (Vorbroke et al., 1995). In all babies described to date with SP-B deficiency, the genetic mutation has been inherited from the parents (autosomal recessive) rather than occurring as a spontaneous mutation (Hamvas et al., 1994). Although multiple genetic mutations have been described, approximately 70% of affected babies carry the 121ins2 mutation (Dargaville and Copnell, 2006). In a series of term babies referred for genetic evaluation of unexplained respiratory failure, 2 of 17 had detectable mutations of the SP-B sequence (Somaschini et al., 2007).

Almost all babies with recognized deficiency of SP-B develop clinical signs of severe respiratory distress, including tachypnea, grunting, and retractions, within the first several hours of life. As for preterm newborns with HMD, CXRs classically reveal diffuse, hazy air space disease with visible air bronchograms. Severe PH may be a prominent feature of the disease. Treatment with surfactant is either ineffective or unsustainable, and progressive respiratory failure is the rule (Hamvas, 2006). Lung transplant is currently the only effective long-term treatment, with both short-term and long-term outcomes similar to those for other infants undergoing lung transplant (Palomar et al., 2006).

Analysis of fluid obtained by BAL/tracheal aspirate from babies with SP-B deficiency should fail to detect any immunoreactive SP-B. The presence of pro-SP-C increases suspicion of SP-B deficiency because intact SP-B is necessary for normal posttranslational processing of the protein to mature SP-C. Histologic findings include alveolar cell hyperplasia, interstitial thickening, and variable degrees of fibrosis and alveolar proteinosis. Staining of lung tissue for pro-SP-B is variable, but staining for mature SP-B should be minimal (because of cross-reactivity with epitopes on pro-SP-B) or absent. Initial DNA analysis focuses on the 121ins2 mutation. More exhaustive testing for other known mutations is warranted if initial testing is negative.

Surfactant-Associated Protein C Deficiency

Mature SP-C is a 35 amino acid hydrophobic protein. SP-C is believed to enhance spreading of surfactant and to participate in

normal surfactant catabolism (Whitsett et al., 2015). As with SP-B, multiple mutations of SP-C have been described; however, most of these mutations of the gene that encodes SP-C arise spontaneously and result in sporadic disease. Whether the abnormal phenotype associated with SP-C deficiency arises from dysfunction of the alveolar surfactant or from accumulation of abnormal cellular SP-C and consequent type II cell injury is not known.

In contrast to babies with SP-B deficiency, babies with SP-C deficiency have a wide range of clinical presentations. Some may develop symptoms within the first several hours of life, similar to SP-B deficiency, whereas others present later in childhood or in adulthood with interstitial lung disease. In one series, half of children with SP-C deficiency presented in the neonatal period, and mortality was reported as 15% (Guillot et al., 2009). The reasons that underlie the variable onset, presentation, and severity of SP-C deficiency are not fully understood, but it is suggested that those individuals whose SP-C mutation lies within the specific BRICHOS chromosomal domain are at higher risk of neonatal presentation (Thouvenin et al., 2010). Corticosteroids are the mainstay of treatment of infants with SP-C deficiency, although many centers also administer azithromycin and/or hydroxychloroquine (Thouvenin et al., 2010).

In common with SP-B deficiency, the lung histopathologic features of patients with SP-C deficiency are nonspecific and widely variable. Common findings include accumulation of alveolar protein and macrophages and epithelial cell hyperplasia. Ultrastructural examination may reveal disorganized lamellar bodies with aggregates of small vesicles with electron-dense cores in the type II cells (Nogee et al., 2001). Allele-specific testing using the polymerase chain reaction for the most common 173T mutation provides an initial screen for SP-C deficiency. If the screen is negative, direct sequencing of the entire SP-C gene should be undertaken.

Adenosine Triphosphate–Binding Cassette Subfamily A Member 3 Deficiency

The ATP-binding cassette transporter proteins are essential for normal transport of compounds in numerous biologic systems (Mulugeta et al., 2002). Deficiencies of individual ATP-binding cassettes have been associated with clinical diseases in a number of different organ systems. ABCA3 is highly expressed in the lung and is involved in the transport of lipids. Individuals lacking the gene for ABCA3 have abnormal accumulation of surfactant-rich lamellar bodies within their type II alveolar cells, with apparent inability to transport surfactant into the alveolar space. Shulenin et al. (2004) detailed a variety of mutations within the ABCA3 gene in a substantial portion of term infants with unexplained respiratory failure and suspected surfactant protein deficiency.

The age at presentation for individuals with ABCA3 deficiency is highly variable, ranging from the immediate newborn period to later in childhood. There may be a family history of consanguinity. Clinical manifestations of disease in the neonate may be indistinguishable from those of neonates with SP-B deficiency, with onset of respiratory failure within hours of birth. The disease may be progressive and fatal. In addition, ABCA3 deficiency may also manifest itself as severe PPHN (Kunig et al., 2007). The treatment options for ABCA3 deficiency are limited. Some children undergo lung transplant, and recent case reports suggest that some patients may respond to corticosteroids, azithromycin, or hydroxychloroquine (Hayes et al., 2012; Thouvenin et al., 2013; Williamson and Wallis, 2014). It has been reported that milder, transient neonatal symptoms may not prompt a diagnostic evaluation in the newborn period, although recurrent pulmonary symptoms may lead to later investigation (Doan et al., 2007). These reports raise the possibility that

deficiency of ABCA3 may be underrecognized in infants or children with a mild or normal phenotype.

The predominant pathologic findings of neonates with ABCA3 deficiency with neonatal respiratory failure include alveolar proteinosis (Bullard et al., 2006), type II cell hyperplasia with dense lamellar bodies, and accumulation of alveolar macrophages in the distal air space. Inheritance is believed to be autosomal recessive. Unlike SP-B deficiency, a single predominant mutation has not been described; rather, multiple distinct mutations affecting different protein domains have been identified (Brash et al., 2006).

Thyroid Transcription Factor 1 Gene Mutation

Recent studies demonstrate that mutations of the gene encoding thyroid transcription factor (TTF)-1 (*NKX2-1*), which is expressed in the thyroid, lung, and brain, can result in neonatal respiratory failure. TTF-1 regulates structural lung development and plays a key role in the expression of SP-B, SP-C, and ABCA3. Histologic findings from these patients are heterogeneous and not diagnostic. Hamvas et al. (2013) reported a series of 21 patients with *NKX2-1* mutations, 17 of whom had neonatal RDS (with or without PPHN). Some of these patients also had thyroid and/or brain abnormalities, while others had only respiratory disease evident at the time of diagnosis.

Surfactant-Associated Proteins A and D

Although lung structural abnormalities have been described in mice lacking SP-A and SP-D, no phenotype attributable to abnormalities of either of these surfactant-associated proteins has been described in human infants. Recent work suggests a role for mutations in the gene that encodes surfactant-associated protein A (SP-A) in adult-onset pulmonary fibrosis in rare circumstances (Whitsett et al., 2015).

Interstitial Lung Disease

The interstitial lung diseases that occur in infancy are a heterogeneous group of disorders that overlap with the surfactant protein disorders and may involve one or more of the several components of the lung. All produce considerable morbidity and mortality. Detailing each individually is beyond the scope of this chapter, but two, alveolar capillary dysplasia with misalignment of pulmonary veins (ACD/MPV) and pulmonary interstitial glycogenosis, have attracted considerable attention in recent years (Deterding, 2010; Hamvas et al., 2013; Whitsett et al., 2015).

Alveolar Capillary Dysplasia/Misalignment of Pulmonary Veins

ACD/MPV results from severe developmental abnormalities of the structure of the pulmonary circulation. In particular, alveolar capillary density is reduced, and capillaries typically reside in the center of abnormally widened alveolar walls rather than immediately proximate to the alveolar epithelium and air space. An additional histologic hallmark of the disease is abnormally positioned pulmonary veins, which are adjacent to the terminal bronchioles (Langston, 1991). Most newborns with ACD/MPV experience respiratory failure and PPHN within the first several days of life. For reasons that are poorly understood, presentation may be delayed in some babies. The typical course of ACD/MPV is refractory respiratory failure and pulmonary hypertension, which ultimately lead to death. Some babies may respond to pulmonary vasodilators but only transiently (Bishop et al., 2011). Stankiewicz et al. (2009) documented deletions of the Forkhead Box (FOX) transcription

factor gene cluster on chromosome 16 in a series of ACD/MPV patients. Depending on the underlying chromosomal abnormality, patients with ACD/MPV may also have other malformations, most notably of the gastrointestinal, genitourinary, and cardiovascular systems.

Pulmonary Interstitial Glycogenosis

Pulmonary interstitial glycogenosis (PIG) is an interstitial lung disease thought to be unique to infants that is characterized by a thickened lung interstitium and the accumulation of intracellular glycogen in immature interstitial cells (Canakis et al., 2002; Dishop, 2011). It has been postulated that PIG represents a developmental lung disorder rather than one resulting from inflammation or other precipitants. Infants with PIG typically develop respiratory symptoms in the first few days of life, including tachypnea and hypoxemia; many require a period of assisted ventilation. Many infants with biopsy-proven PIG have been treated with pulse steroid therapy, and often respiratory symptoms abate or resolve altogether in the first year of life. Whether steroid treatment accelerates the abatement process has not been established and remains controversial (Das et al., 2011).

Congenital Diaphragmatic Hernia

CDH is a complex clinical syndrome caused by a developmental defect in the diaphragm, resulting in a spectrum of potentially severe cardiopulmonary abnormalities (Fig. 47.2). The estimated incidence of CDH ranges from approximately 1 in 2500 to 1 in 7000 liveborn babies (Prober, 2007). Approximately 80%–85% of diaphragmatic hernias occur on the left side. In rare circumstances they may be bilateral. Anatomically, CDH is classically divided by location into posterolateral (Bochdalek) defects, retrosternal anterior (Morgagni) defects, and other anterior or central defects. The vast majority, 90%–95%, are of the Bochdalek type. However, these classic anatomic distinctions cannot always be clearly differentiated (Prober, 2008). Moreover, the implications of hernia location on the severity of illness or mortality are not clearly defined (Wynn et al., 2013).

• **Fig. 47.2** Chest radiograph of an infant with left-sided congenital diaphragmatic hernia. Note the proper position of the orogastric tube and umbilical venous catheter.

As many as 30%–40% of babies with CDH have additional congenital anomalies, most commonly of the heart, central nervous system, and genitourinary system. The remaining 60%–70% of babies have isolated CDH without other identifiable major anatomic malformations. CDH may occur as an element of several well-recognized syndromes or of a chromosomal abnormality (particularly trisomy 18). In babies with CDH but without a recognized genetic syndrome, 10%–15% have heart defects, most commonly septal defects, conotruncal malformations, and obstruction of the left ventricular outflow tract (Lin et al., 2007). Coexisting cardiac disease complicates the management of babies with CDH and likely increases mortality. There is growing interest in the potential for fetal tracheal occlusion in the most severe cases diagnosed prenatally, but there is insufficient evidence to warrant routine use (Grivell et al., 2015).

Medical management of the newborn with a CDH remains one of the most complex and challenging situations for a neonatologist. A host of interrelated issues must be considered, including optimal mechanical ventilation strategies, the presence and treatment of pulmonary hypertension, evaluation of cardiac performance, and consideration of support with ECMO. Unfortunately, owing to the relative infrequency of CDH, definitive studies guiding clinical decisions in the management of these babies are lacking.

The optimal mode and strategy of mechanical ventilation in CDH have not been definitively established. Previously, aggressive hyperventilation and alkalinization as a means to lower PVR were advocated (Bohn et al., 1987). More recently, with the recognition that aggressive mechanical ventilation to the point of hyperventilation may cause significant iatrogenic lung injury and worsen outcome, this approach has generally been abandoned (Sakurai et al., 1999). However, prospective trials to clearly guide the ventilator strategy are lacking. Many experts now advocate a gentle ventilation strategy that minimizes peak inspiratory pressure, targets arterial partial pressure of carbon dioxide (PaCO_2) levels between 40 and 60 Torr, and tolerates postductal desaturation if preductal saturations are adequate. If a conventional ventilator strategy is used and the peak inspiratory pressures needed to achieve these goals are unacceptably high (generally 25 to 30 cmH_2O), transition to high-frequency oscillatory ventilation (HFOV) is undertaken (Finer et al., 1998; Bohn, 2002; Boloker et al., 2002). As an alternative, some advocate earlier or initial use of HFOV (Frenckner et al., 1997; Reyes et al., 1998; Bagolan et al., 2004). Although definitive evidence in support of this gentle ventilation strategy is lacking owing to the retrospective nature of the reports cited, mortality in several centers has fallen coincident with adoption of this approach.

PH is a well-recognized complication of CDH, and the severity of PH at 1 month of life correlates with increased mortality (Wynn et al., 2013). Decreased cross-sectional area of the pulmonary circulation, structural remodeling of the pulmonary vessels, and diminished size and function of the left ventricle have all been implicated in the PH associated with CDH. Newborns with CDH should all undergo early echocardiography to ascertain the presence of associated heart defects, to assess the degree of pulmonary hypertension, and to evaluate the function of the left and right ventricles. Treatment of early PH in babies with CDH is controversial. Treatment with iNO did not reduce mortality among a group of infants with CDH in whom aggressive medical therapy had failed (Neonatal Inhaled Nitric Oxide Study Group, 1997). Moreover, newborns treated with iNO in that study more frequently required ECMO than the control group, likely related to the adverse effects

of pulmonary vasodilation in the presence of severe left-ventricular dysfunction, potentially worsening systemic hemodynamics. Current evidence does not support the routine use of iNO in the first 24 hours after birth in infants with CDH. Rather, its use should be limited to those babies with optimized lung inflation and well-defined PH who do not have evidence of impaired left-ventricular performance and right ventricle-dependent systemic blood flow (Kinsella et al., 2005; Abman et al., 2016). Other pharmacologic pulmonary vasodilators to treat acute PH in babies with CDH have not been carefully evaluated. In babies with severe PH and a closed ductus arteriosus, consideration should be given to restoration of ductal patency with prostaglandin infusion, to allow the right ventricle to serve as a source of systemic blood flow (Kinsella et al., 2005; Abman et al., 2016).

Animal models of CDH demonstrate biochemical and physiologic evidence of surfactant deficiency (Glick et al., 1992). In these models, surfactant replacement lowers PVR and improves gas exchange and lung mechanics (Wilcox et al., 1994; O'Toole et al., 1996). Studies of human babies with CDH also suggest a delay in surfactant maturation, and postmortem studies of babies with CDH commonly demonstrate the presence of hyaline membranes (Hisanaga et al., 1984; Moya et al., 1995). Taken together, the findings of studies raise the possibility that surfactant replacement therapy might have a role in the management of babies with CDH. Although initial anecdotal evidence supported this possibility, a more recent retrospective study of more than 500 term babies with CDH suggested that surfactant treatment was associated with greater ECMO use, increased incidence of chronic lung disease, and reduced overall survival (Van Meurs and Congenital Diaphragmatic Hernia Study Group, 2004). These findings strongly argue against the routine use of surfactant replacement in babies with CDH.

Owing to the infrequency of CDH and the wide variability in therapeutic approaches (both among centers and over time at individual centers), few studies of long-term outcome have been published. Studies suggest that babies born with CDH are at risk of a number of serious long-term morbidities, including impaired neurodevelopmental outcome, wheezing/asthma, protracted pulmonary hypertension, sensorineural hearing loss, gastroesophageal reflux, scoliosis, and pectus excavatum (Peetsold et al., 2009). One study reports lower than anticipated scores on tests of intelligence and adaptive behavior among 11 CDH survivors who were not treated with ECMO (Bouman et al., 2000). Stolar et al. (1995) reported that among 51 babies treated with ECMO, the subset of those with CDH had worse cognitive outcome than those with alternative underlying diagnoses. Neurologic (physical) testing was similar between the two groups. Wynn et al. (2013) reported that CDH patients had lower developmental scores at 2 years of age and that developmental delays were associated with the need for ECMO and lower socioeconomic status. Although concerning, these findings must be interpreted with caution, because the mean age at evaluation was less than 3 years. CDH is also associated with a high rate of sensorineural hearing loss (SNHL), nearly 50% in one study (Morini et al., 2008). The causes that underlie the high incidence of SNHL in this population, and whether it represents a genetic/anatomic predisposition or is a result of treatment-related risk factors, have yet to be clarified.

As might be expected, several cardiopulmonary sequelae of CDH have been reported. In a follow-up study of adolescents born with CDH, Trachsel et al. (2005) reported several abnormalities elicited by pulmonary function testing. Compared with normal controls, CDH survivors demonstrated mild to moderate airway obstruction,

and nearly half were responsive to bronchodilators. CDH patients also had decreased inspiratory muscle strength and maximum minute ventilation. In spite of these findings, these adolescents generally had minimal compromise of daily activities. The persistence of PH in some patients with CDH remains a major concern. After CDH repair and with readiness for removal from mechanical ventilation, some infants with underlying PH develop suprasystemic pulmonary artery pressures with discontinuation of iNO treatment. Kinsella et al. (2003) reported successful ongoing treatment of these babies with delivery of noninvasive iNO treatment via a nasal cannula. Schwartz et al. (1999) report that 38% of their CDH patients who required ECMO had echocardiographic evidence of PH well beyond the newborn period, with a mean follow-up age of 3.2 years. Importantly, most of those children had no apparent physical signs or symptoms of PH, supporting the need for proactive, ongoing surveillance. Although recent studies focused on the long-term follow-up of pulmonary vascular disease in these patients are lacking, the American Academy of Pediatrics recommends serial echocardiographic evaluation of children with CDH who have persistent PH after repair (Lally and Engle, 2008). Newer pharmacologic agents for treatment of PH, such as phosphodiesterase inhibitors (sildenafil) or endothelin antagonists such as bosentan, may offer effective longer-term therapy for PH but have not been investigated in this population.

Postnatal nutrition presents a major challenge for many survivors of CDH. Among 121 CDH survivors, Muratore et al. (2001) reported that one-third had failure to thrive requiring the placement of a gastrostomy tube for the provision of adequate calories, and 25% demonstrated evidence of oral aversion. Many reports have documented the high incidence of gastroesophageal reflux after repair of CDH, and studies have reported that 12%–28% require fundoplication for severe gastroesophageal reflux (Fasching et al., 2000; Diamond et al., 2007; Su et al., 2007).

Summary

The initial evaluation of respiratory distress/hypoxemia in the term newborn presents one of the most difficult challenges faced by pediatricians and neonatologists. An ordered approach using information derived from the history, physical examination, pulse oximetry measurements, radiographic and laboratory measurements, and echocardiography can help elucidate the cause of hypoxemia

Pulmonary Hypoplasia

In the absence of a diaphragmatic hernia, pulmonary hypoplasia and respiratory failure can develop in association with a number of other conditions. An extensive list of conditions associated with pulmonary hypoplasia has been generated, but most cause either restriction of normal fetal breathing motion or compression of the developing lung. Thus among the most common causes of pulmonary hypoplasia are low amniotic fluid volumes, neuromuscular disorders, pleural effusions/chylothoraces, and space-occupying lung lesions.

Inadequate amniotic fluid volume to allow normal fetal breathing can result from a number of circumstances. Because fetal urine is a primary contributor to amniotic fluid volume, any abnormality of renal development that limits fetal urine production or urine flow can result in pulmonary hypoplasia. In addition, preterm premature rupture of membranes, particularly with persistent leak of amniotic fluid, can result in pulmonary hypoplasia. For a more comprehensive discussion of preterm premature rupture of membranes and pulmonary hypoplasia in preterm infants, see Chapter 46.

Definitive diagnosis of pulmonary hypoplasia can be made only at autopsy. Norms have been established for both the gestational age–corrected ratio of lung weight to body weight and for histologic evaluation of radial alveolar counts (Askenazi and Perlman, 1979; Lauria et al., 1995). Clinical criteria for pulmonary hypoplasia are less well defined. Neonates may have a bell-shaped chest and elevated diaphragms on CXR. Management of pulmonary hypoplasia should focus on maximizing lung inflation while avoiding pneumothorax, the incidence of which ranges widely, depending on the study (Leonidas et al., 1982; Klaassen et al., 2007). Ventilator strategies include permissive hypercapnia, to minimize lung injury, and the use of HFOV. If PH is defined echocardiographically, use of iNO should be considered. With sustained postnatal ventilatory support, the PH associated with pulmonary hypoplasia may resolve over time.

and respiratory failure and direct each step of clinical management. Recognizing the important contributions of parenchymal lung disease, pulmonary vasoconstriction, and cardiac performance is critical to successful clinical management of the term newborn with respiratory failure.

Bronchopulmonary Dysplasia

ROBERTA L. KELLER AND ROBERTA A. BALLARD

KEY POINTS

- Bronchopulmonary dysplasia (BPD) is a heterogeneous disorder.
- The cause is multifactorial.
- Early nutritional and ventilatory support are important preventive strategies.
- Effective pharmacologic strategies remain a challenge, although caffeine use—for prevention—has been widely adopted.
- Extremely preterm infants are at highest risk for BPD (genetic predisposition, unfavorable fetal environment, severe early cardiopulmonary illness), but there are limited preventive options.

Historical Overview

Bronchopulmonary dysplasia (BPD), also referred to as *chronic lung disease of prematurity*, is the most common chronic lung disease of childhood. BPD was first described by [Northway et al. in 1967](#) as a severe chronic lung injury in premature infants who survived hyaline membrane disease after treatment with mechanical ventilation and oxygen ([Northway et al., 1967](#)). Four distinct clinical stages were described radiographically and pathologically, progressing from typical respiratory distress syndrome (RDS), with alveolar interstitial edema as well as atelectasis, to massive fibrosis and consolidation of the lung with areas of cystic emphysema and overinflation.

BPD, as originally described, occurred predominantly in preterm infants born at 30 to 34 weeks' gestation with a history of severe respiratory distress necessitating aggressive ventilatory support and high levels of oxygen exposure for a prolonged period of time. These infants were born before the introduction of prenatal corticosteroids or postnatal surfactant replacement therapy and at a time when ventilators were first being adapted for use in the newborn.

Since that time, much has been learned about BPD, and the disorder as originally described has become rare. The infants who are more commonly affected with BPD today are those of extremely low birth weight, born at less than 26 weeks' gestation. Following exposure to prenatal corticosteroids, combined with postnatal exogenous surfactant for treatment of RDS, these infants initially frequently do remarkably well, requiring low levels of supplemental oxygen and ventilatory support. They often have a subsequent period of several days during which there is minimal or no requirement for ventilatory support, before entering into a more chronic phase of variable requirements for assisted ventilation and

supplemental oxygen. The form of BPD seen in the contemporary extremely preterm infant who has had minimal initial respiratory distress has been termed the *new BPD*, with arrested lung development affecting both alveologenesis and the pulmonary vascular bed ([Jobe, 1999; Abman, 2001, 2008](#)).

Although the initial definition of BPD was a persistent requirement for supplemental oxygen 28 days after birth, in an attempt to better define the functional implications of abnormal postnatal lung development in extremely preterm newborns, the need for oxygen at 36 weeks' postmenstrual age (PMA) was found to be a better predictor of later pulmonary illness in extremely premature infants ([Shennan et al., 1988](#)). The definition of BPD was subsequently reviewed at a National Institutes of Health (NIH)-sponsored workshop ([Jobe and Bancalari, 2001](#)). This group proposed diagnostic criteria for increasing severity of BPD, including the receipt of oxygen supplementation of varying degrees and assisted ventilation (continuous positive airway pressure [CPAP] and/or mechanical ventilation) at 36 weeks' PMA ([Table 48.1](#)). Concurrently, a physiologic challenge (protocolized withdrawal of supplemental oxygen and nasal cannula flow to room air, as tolerated) was being developed and tested ([Walsh et al., 2003, 2004](#)). In these initial studies, the use of the physiologic challenge reduced the incidence of BPD by almost 30%, with some decrease in center variability ([Walsh et al., 2004](#)). However, more recent reports from the same study group (the NIH-sponsored Neonatal Research Network [NRN]) have suggested less of an effect of the physiologic challenge on the incidence of BPD (the "physiologic definition"), only decreasing BPD rates from 42% to 40% ([Stoll et al., 2010](#)). Using the severity criteria proposed in the NIH workshop, data from the NRN demonstrated increasing frequency of respiratory morbidity and neurodevelopmental impairment at follow-up with increasing severity of BPD ([Ehrenkranz et al., 2005](#)). Furthermore, the definition of BPD using the need for supplemental oxygen alone was equally predictive of later pulmonary morbidity, as was the need for oxygen plus an abnormal chest radiograph. Similarly, increasing severity of BPD by the clinical classification was associated with persistence of respiratory morbidity over the first year after hospital discharge in the NIH-funded Prematurity and Respiratory Outcomes Program ([Keller et al., 2016a](#)). These data, along with the data from [Shennan et al. \(1988\)](#), which did not incorporate radiographic findings in their clinical definition of BPD, have largely eliminated the requirement for abnormal chest radiograph in the definition of BPD. However, with the exception of infants who undergo a physiologic challenge, infants receiving nasal cannula support (which can variably provide positive end-expiratory pressure

TABLE 48.1 Diagnostic Criteria for Bronchopulmonary DysplasiaTreatment with $\text{FiO}_2 > 0.21$ for at least 28 days

PLUS

Failure of room air challenge test at 36 weeks' postmenstrual age

Classification of Severity

| | |
|----------|---|
| Mild | Requires ≤ 0.30 effective FiO_2^a |
| Moderate | Requires > 0.30 effective FiO_2^a |
| Severe | Requires ventilatory support, usually with oxygen |

^aEffective FiO_2 is based on infant's weight and the concentration and flow of oxygen through a nasal cannula or in a hood. FiO_2 , Fraction of inspired oxygen.Data from Jobe AH, Bancalari E. Bronchopulmonary dysplasia. *Am J Respir Crit Care Med*. 2001;163:1723–1729.

[PEEP]) without supplemental oxygen (fraction of inspired oxygen [FiO_2] 0.21) are generally not given a diagnosis of BPD, which may not accurately reflect an infant's respiratory status (Sreenan et al., 2001; PoinDEXter et al., 2015).

In the presurfactant era, there was remarkable consistency in the postconceptual age at which infants surviving without later pulmonary morbidity were weaned off supplemental oxygen (Shennan et al., 1988). Subsequent studies have shown substantial proportions of infants with no BPD that do have later respiratory morbidity and relatively high proportions of infants with BPD that have no respiratory morbidity (Ehrenkranz et al., 2005; Keller et al., 2016a). Data from the Collaborative Home Infant Monitoring Evaluation Study demonstrate higher rates of apnea and desaturation in preterm infants at term-adjusted age and beyond, suggesting that persistence of oxygen supplementation in some former preterm infants may be related to dysmaturation of respiratory control (Ramanathan et al., 2001; Hunt et al., 2011). Consistent with this possibility, Coste et al. (2015) showed that former preterm infants undergoing a physiologic challenge test had increased frequency of periodic breathing. Thus as survival for the most immature newborns has improved following the introduction of surfactant replacement therapy and the broadening use of prenatal corticosteroids, it may be that later assessments of pulmonary status, at 40 weeks' PMA, for example, will better assess for differences in underlying lung function and will be better markers of respiratory morbidity through infancy and beyond (Davis et al., 2002; Keller et al., 2009).

Epidemiology

Although BPD is now relatively rare in infants born beyond 30 weeks' gestation, its incidence has been increasing in extremely low GA newborns, particularly those born at less than 26 weeks' gestation, as survival has improved. Data over a 20-year period for infants with birth weights ranging from 401 to 1500 grams and born at 22 to 28 weeks' gestation from the NRN demonstrate that the incidence of BPD at 36 weeks' postconceptional age increased from 36% in 1993–1997 to 45% in 2008–2012, while survival increased from 72%–76% over the same period (Stoll et al., 2015). In the most recent era (2008–2012), rates of BPD in infants surviving at 36 weeks' PMA were 88%, 79%, 69%, 57%, 50%, 36%, and 24% for infants of 22, 23, 24, 25, 26, 27,

and 28 weeks' gestation, respectively. Overall, survival without morbidity was unchanged for infants greater than 24 weeks' gestation but increased in less mature infants, carrying a costly chronic health burden in these most premature infants (Watson et al., 2009; Stoll et al. 2015). Among infants less than 29 weeks' gestation in the California Perinatal Quality Care Collaborative (CPQCC), rates of BPD or death before 36 weeks' PMA by birth weight were 81% among infants less than 750 grams, 49% for 751–999 grams, 25% for infants 1000–1249 grams, and 13% for infants 1250–1500 grams. As these data show, increased rates of BPD or death by 36 weeks' PMA are associated with lower GA and birth weight. Male sex and higher level of respiratory support are also consistently associated with increased rates of BPD or death (Ambalavanan et al. 2011; Laughon et al., 2011). Both the NRN and CPQCC report wide variability in the incidence of this composite outcome by center (Ambalavanan et al., 2011; Lapcharoensap et al., 2015). In CPQCC, the level of complexity of care was associated with rates of BPD or death, with centers that provide the most complex level of service demonstrating the lowest rates of adverse outcome (Lapcharoensap et al., 2015). The NRN analysis identified several practices that were independently associated with both BPD or death and center (i.e., practices that varied by center), but differences in rates of BPD persisted even when accounting for those identified center differences and infant baseline characteristics, indicating that there were other, unaccounted for center-specific or infant-specific differences (Ambalavanan et al., 2011).

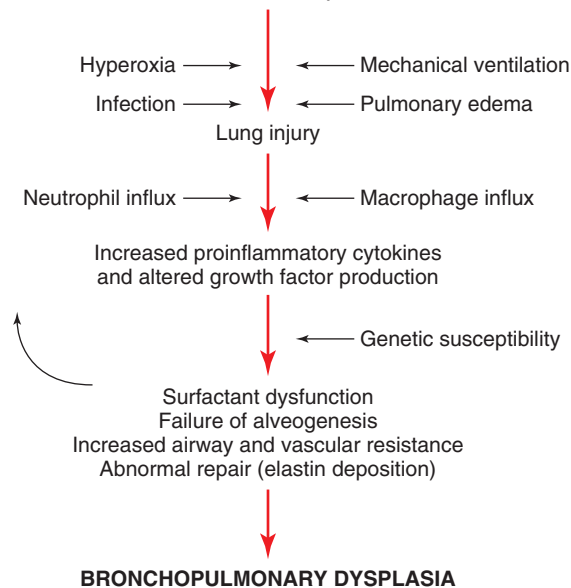

With respect to level of respiratory support, the persistence of mechanical ventilation and increasing degrees of supplemental oxygen have been associated with increased rates of BPD. Using data from the NRN, Laughon et al. demonstrated that the relative importance of the degree of respiratory support increases with respect to the outcome of BPD or death with advancing postnatal age (Laughon et al., 2011). At less than 7 days of age, GA has the most influence on this outcome, but at 7 to 21 days, the degree of respiratory support has the greatest influence. Similarly, Ambalavanan found that mechanical ventilation in the first 7 days was independently associated with BPD or death (Ambalavanan et al., 2011). In the Extremely Low Gestational Age Newborn study (infants < 28 weeks' gestation), rates of BPD in survivors at 36 weeks' PMA correlated with the pattern of supplemental oxygen exposure over the first 14 days of life (Laughon et al., 2009a). The overall incidence of BPD was 51%, but infants with a persistent low level of oxygen supplementation had the lowest rate of BPD (17%), infants with a deterioration in their pulmonary status (low initial levels of oxygen supplementation increasing in the second week) had an intermediate incidence of BPD (51%), and infants with persistently higher oxygen requirements had the highest rate of BPD (67%). Mechanical ventilation was also closely associated with these patterns of oxygen supplementation. At 7 days, 21%, 57%, and 84% of the low oxygen, pulmonary deterioration, and persistent high oxygen groups were receiving mechanical ventilation, respectively. These data are consistent with the selection of ventilated infants at 7 to 14 days of age for study of strategies to prevent BPD, given their high risk for adverse respiratory outcome (Ballard et al., 2016).

Pathobiology

The cause of BPD is clearly multifactorial and involves derangements in multiple aspects of lung function (e.g., surfactant production and function), repair from injury (e.g. elastin deposition), and growth and development (e.g., alveologensis and microvascular

development). Various factors contribute to this process, including a susceptible host with immature lung structure and developmental deficiencies of factors crucial to lung development and function such as surfactant, nitric oxide, innate immune defense, and antioxidant capability (Fig. 48.1). Interestingly, structural differences in the placentas of extremely low GA infants consistent with maternal underperfusion are associated with the development of

Premature lung with developmental deficiencies (surfactant, nitric oxide, immune defense, etc.) and immature alveoli

• **Fig. 48.1** The Pathogenesis of Bronchopulmonary Dysplasia. Lung injury in the immature lung secondary to hyperoxia, mechanical ventilation, and infection initiates an inflammatory response with an altered milieu of growth and inflammatory factors. Continuing insults contribute to the long-term changes in lung structure that characterize bronchopulmonary dysplasia.

BPD (Mestan et al., 2014). Biochemical changes that influence fetal lung development and/or some degree of fetal nutritional deprivation can accompany these structural differences. Thus both fetal and postnatal nutritional deficiencies, and the resulting growth failure, may cause or exacerbate lung structural abnormalities and impair the ability of these infants to recover from early lung injury.

Pathologic Findings in the “New” Form of the Disease

In the chronic stage of BPD as originally described, the lung had extensive alveolar fibrosis, airway abnormalities, and pulmonary vascular remodeling (Northway et al., 1967; Bonikos et al., 1976). In contrast, the lungs are more uniformly inflated with minimal airway injury and less prominent fibrosis in the new BPD. The major abnormalities in infants dying with BPD are a decrease in alveolar number with less septation (referred to as *alveolar hypoplasia and alveolar simplification*) and dysregulated microvascular growth (Husain et al., 1998; Coalson et al., 1999; Bhatt et al., 2001; Maniscalco et al., 2002; De Paepe et al., 2006, 2008). In the very preterm infants in whom this new BPD is seen (Fig. 48.2), the lung is in the late canalicular or early saccular stage of development at the time of birth. Consistent with extremely preterm birth, investigators have noted arrested lung development in the saccular stage at autopsy in infants with prolonged ventilation, despite ongoing endothelial cell proliferation (De Paepe et al., 2006). A number of factors that interfere with postnatal alveogenesis may contribute to the disordered lung development seen in contemporary premature newborns.

Multifactorial Etiologic Factors

Host Susceptibility and Genetic Predisposition

Although the most important factor in the pathogenesis of BPD is prematurity, infants with fetal growth restriction are at increased

• **Fig. 48.2** Radiographs of Bronchopulmonary Dysplasia (BPD) Characteristic of the “New and “Old” Forms of the Disease. (A) Bilateral fine granular opacification consistent with atelectasis and/or edema, characteristic of the “new” BPD. (B) Bilateral coarse interstitial opacification consistent with fibrosis and/or edema and areas of hyperinflation, characteristic of the “old” BPD.

risk (Lal et al., 2003; Bose et al., 2009; Durrmeyer et al., 2012; Soudée et al., 2014). In addition, it has been known for some time that infants born to some families are more likely to have RDS at any given GA than those born to other families. Twin studies have supported this clinical impression, revealing that 50%–80% of the variance in the occurrence of BPD is due to genetic factors (Bhandari et al., 2006; Lavoie et al., 2008). In addition, a family history of asthma may increase the risk of BPD, although in the most recent study, this effect was present only in the absence of prenatal steroid exposure (Hagan et al., 1995; Gage et al. 2015). Several studies have described the association of BPD with single nucleotide polymorphisms for genes involved in the inflammatory response, innate immunity, angiogenesis, surfactant function, and the extracellular matrix such as interleukins, collectins, surfactant-associated proteins, and proteases. Although a recent genome-wide association study failed to replicate previous studies, the analyses suggested a dominant relationship between genetic variants and the BPD phenotype and reinforced the possibility that previous work had identified important pathways in the pathogenesis of BPD, despite the fact that the patient population had greater racial and ethnic diversity than previous studies (Wang et al., 2013). An analysis of rare variants identified three pathways as candidates, involving collagen fibril organization, embryonic epithelial morphogenesis, and regulation of the Wnt signaling pathway (involved in cell-to-cell interactions and stem cell renewal) (Li et al., 2015). The genes identified in this work were also upregulated in lungs of rats exposed to hyperoxia. These investigations may ultimately lead to more directed therapies for high-risk, susceptible infants, as variants may be associated with enhanced response to environmental insults or mitigating therapies.

Inflammation

The fetal-derived inflammatory response syndrome (FIRS) plays a major role in preterm birth and the development of BPD (Yoon et al., 1999; Kim et al., 2015). This fetal response may be triggered by microbial invasion of the amniotic cavity or sterile histologic acute chorioamnionitis. This inflammation primes the preterm lung for injury caused by neonatal inflammatory insults related to supplemental oxygen exposure (with oxidant damage) and ventilation with volutrauma. Interestingly, in a large prospective study of extremely low GA newborns with very high rates (90%) of prenatal glucocorticoid exposure, neither histologic chorioamnionitis nor the recovery of specific or multiple placental microorganisms were associated with later development of BPD (Bose et al., 2009). Study design (e.g., clinical vs histologic chorioamnionitis and lack of adjustment for GA and/or birth weight) has been implicated as the reason for the inconsistent relationship of chorioamnionitis and BPD in contemporary cohorts, with the potent antiinflammatory effects of prenatal steroid exposure potentially providing a biologic rationale for a diminished effect of chorioamnionitis (Been et al., 2009; Hartling et al., 2011).

Despite this, fetal and neonatal inflammatory responses are well documented and associated with adverse neonatal outcomes. The fetal inflammatory response has been demonstrated by cytokine and chemokine elevations in amniotic fluid and cord blood (Kim et al., 2015). Increased levels of interleukin (IL)-6 are the hallmark of FIRS, but IL-1 α and IL-1 β , IL-10, IL-8, and other chemokines are also elevated. This inflammatory response is reflected in increased numbers of neutrophils in tracheal aspirate samples as early as the second day of life (Arnon et al., 1993). Although alveolar macrophages are essential for recognition, ingestion, and elimination of

lung pathogens, they also produce fibroblast, epithelial, and endothelial cell growth factors, leading to lung tissue repair. In addition, they can have deleterious effects through release of oxygen radicals and can release fibronectin, a large glycoprotein that is a growth factor for fibroblasts, as well as releasing the growth factor transforming growth factor (TGF)- β , which stimulates the growth of mesenchymal cells and inhibits proliferation of epithelial cells. Multiple markers of inflammation (cytokines, chemokines, and other inflammatory factors) have been found in high concentrations in lung lavage fluid of infants in whom BPD develops. Box 48.1 lists inflammatory response factors quantified in tracheal aspirate or lavage samples that are often correlated with each other (Merrill et al., 2011) and are associated with the development of BPD in the preterm infant; levels of IL-10, CC10, and vascular endothelial growth factor are decreased in infants that later develop BPD (reviewed in Bose et al., 2008; Ryan et al., 2008; Speer, 2009). Studies of mediators in lung fluid, compared with plasma, may have the advantage of reflecting local lung inflammation rather than the systemic fetal or neonatal inflammatory response, but they are limited to those infants who remain mechanically ventilated via endotracheal tube at any time point. Ambalavanan et al. evaluated systemic inflammatory responses and found relationships consistent with studies of lung fluid: early elevations in plasma concentrations of IL-1 β , IL-6, and interferon- γ were associated with BPD or death in preterm infants (Ambalavanan et al., 2009). A recent secondary analysis of these data, evaluating BPD in survivors, demonstrated higher levels of IL-8 and matrix metalloproteinase-9 and lower levels of granulocyte-macrophage colony-stimulating factor in infants who later developed BPD. Of infants with BPD, those with persistently higher levels of supplemental oxygen had multiple elevations of inflammatory markers (cytokines and chemokines), compared with those with BPD with lower levels of oxygen supplementation (D'Angio et al., 2016). Bose et al. also found systemic inflammatory markers in the first 14 days to be predictive of BPD (Bose et al., 2011). Some of these effects were attenuated in the multivariate model by inclusion of persistent mechanical ventilation at 7 days, suggesting an important relationship between mechanical ventilation and inflammation in the development of BPD.

Neonatal Infection

Airway microbial colonization with a variety of organisms has been associated with a diagnosis of clinical chorioamnionitis, evidence of lung inflammation, and an increased risk of BPD (Groneck et al., 1996; Bhandari et al., 1998; Cordero et al., 2001; Young et al., 2005). Postnatal bacterial sepsis with gram-positive, gram-negative, or fungal organisms has also been associated with an increased risk of BPD (Stoll et al., 2002), although this relationship is not consistent across all studies with adjustment for other clinical risk factors for BPD (Ambalavanan et al., 2011). There has been a lot of interest in the role of fastidious organisms (particularly *Ureaplasma* and *Mycoplasma* species [spp.]) in the development of BPD, with colonization and infection of the placenta, fetus, and newborn broadly studied. A metaanalysis of the recovery of *Ureaplasma* spp. from neonatal airways and BPD demonstrated a significant relationship of organism recovery to BPD (Schelonka et al., 2005). However, there was concern regarding the validity and implications of these published studies: the relationship for BPD determined at 28 days was stronger than the relationship for BPD determined at 36 weeks' PMA, and older studies, those including infants with lower rates of surfactant administration, and those with smaller sample sizes (with more potential for bias), were more likely to demonstrate a positive association with airway colonization. More recent changes in perinatal practices, including the utilization of macrolide antibiotics for latent preterm labor, may affect the application of these study findings. In fact, most recently, the administration of neonatal macrolide antibiotics demonstrates marginal effect on BPD only in infants with *Ureaplasma* colonization (which may occur in up to one-third of preterm infants who do not have intrauterine growth restriction) (Ballard et al., 2011; Ozdemir et al., 2011). Thus if the new BPD in the extremely preterm infant is a syndrome of arrested lung development, it may be that even short-term exposure to microbial organisms and the resultant inflammatory response (augmented by exposure to mechanical ventilation) contribute to the arrest of normal alveolarization and microvascular growth.

Oxygen Toxicity and Oxidative Stress

In the initial cases of BPD reported by Northway et al. (1967), it was clear that exposure to high inspired oxygen concentrations was a factor in development of the disease. Subsequent reports continue to show an association between high levels of supplemental oxygen or prolonged oxygen exposure and the development of BPD in ventilated preterm infants, an effect which may plateau in the first several weeks of life (Wai et al., 2016). Recent studies have shown that even short periods of exposure to higher levels of supplemental oxygen during resuscitation of preterm infants increase rates of BPD (Vento et al., 2009; Kapadia et al., 2013). And, although even a relatively small increase in inhaled oxygen concentration over a period of several weeks may increase respiratory morbidity when applied later in the neonatal course (STOP-ROP Multicenter Study Group, 2000; Askie et al., 2003), studies instituting lower oxygen saturation targets from birth have failed to significantly lower rates of BPD and may increase mortality in the least mature infants (SUPPORT Study Group, 2010; BOOST II United Kingdom Collaborative Group et al., 2013; Schmidt et al., 2013; Darlow et al., 2014; Manja et al., 2015).

In experimental animals, prolonged hyperoxic exposure of varying degrees recapitulates the clinical and morphometric findings of the older and newer forms of BPD (reviewed by Bhandari, 2014),

and oxidative stress and inflammation have been implicated in the pathogenesis of the morphometric changes in these models (Chang et al., 2003, 2013; Ratner et al., 2009). The damage to the lung caused by oxygen toxicity appears to be mediated by reactive oxygen species that are produced during univalent reduction of molecular oxygen. These species include superoxide anion, hydrogen peroxide, and hydroxyl radical. Evidence suggests the presence of an oxidant–antioxidant imbalance in lungs that are at risk for BPD. Both Vento et al. and Kapadia et al. found that short exposure to hyperoxia during newborn resuscitation increased markers of oxidative stress and inflammation of preterm newborns (Vento et al., 2009; Kapadia et al., 2013). Infants resuscitated with higher oxygen concentrations had an increased oxidative balance ratio and higher ratios of oxidized-to-reduced glutathione levels in blood as well as increased urine levels of oxidized proteins and DNA in the first week of life. Extremely preterm infants also had increased systemic markers of inflammation (tumor necrosis factor- α and IL-8) and a shorter duration of mechanical ventilation and supplemental oxygen exposure, as well as decreased rates of BPD, although the latter effect was not significant in a metaanalysis of the subgroup of infants less than 29 weeks' gestation (Vento et al., 2009; Oei et al., 2017). Other observational studies have found higher concentrations of lipid peroxidation metabolites, as well as excess carbonylated proteins, in preterm infants later developing BPD, compared with preterm controls without BPD, further supporting the concept of oxidant–antioxidant imbalance (reviewed in Saugstad, 2003).

Inflammation is concurrent with high oxygen exposure, and in experimental models, inflammation is mitigated by therapies that improve lung structure, such as mesenchymal stem cell transplant (Chang et al., 2013). Antioxidant defenses are decreased in preterm infants, and critical nutrients such as retinoic acid (shown to suppress both superoxide and hydrogen peroxide formation in stimulated neutrophils and macrophages) are deficient (reviewed in Shenai, 1999). Nitric oxide, either endogenous or exogenous in origin, may function as either a prooxidant or antioxidant; no significant differences were seen in plasma carbonylated or nitrosylated protein levels in infants treated with inhaled nitric oxide (iNO) versus placebo in the randomized NO CLD Trial over the first 10 days of gas administration, when iNO dose was 10–20 parts per million (ppm) (Ballard et al., 2008). An early randomized trial of allopurinol, a xanthine oxidase inhibitor studied for its potential neuroprotective effects, demonstrated no differences in the incidence of BPD at 28 days (Russell and Cooke, 1995). Similarly, intratracheal recombinant human superoxide dismutase (rhSOD) did not affect the incidence of BPD at 36 weeks, although treated infants had less pulmonary morbidity than control infants at 1-year follow-up (Davis et al., 2003).

Given the concerns raised in maintaining lower oxygen saturation targets in extremely low GA newborns, and studies demonstrating that higher cumulative supplemental oxygen exposure in this population is associated with increased rates of BPD (Laughon 2009a; Wai et al., 2016), either effective antioxidant therapy, or other strategies that can persistently improve lung function and decrease supplemental oxygen exposure, or a combination of these effects is critical for prevention of BPD. For instance, exogenous surfactant has been shown in vitro to have antioxidant activity, and it transiently decreases the degree of mechanical ventilation support (as measured by the respiratory severity score, equal to mean airway pressure \times inspired oxygen concentration) when given to high-risk preterm infants after the first week of life (Dani et al., 2009; Merrill et al., 2011; Keller et al., 2012). Similarly,

mesenchymal stem cells both provide and activate antioxidant activity in experimental systems, while also decreasing respiratory severity score in extremely preterm newborns (Chang et al., 2014; reviewed by Pierro et al., 2015).

Ventilation With Volutrauma

As is the case with exposure to high oxygen, the association between overdistension of the preterm lung and the development of BPD is well established. Overinflation produces stress fractures of the capillary endothelium, epithelium, and basement membrane. This mechanical injury causes leakage of fluid into the alveolar spaces, with additional inflammatory response and the release of additional proinflammatory cytokines. The relative contribution of high peak inspiratory pressure (PIP) (*barotrauma*) versus overdistension of the lung (*volutrauma*) to lung injury has been a source of some controversy. Hernandez et al. (1989) compared the respective roles of high tidal volume with high PIP in immature New Zealand white rabbits to look at the effect on microvascular permeability in animals that were treated with chest wall restriction with a full-body plaster. Preventing overdistension also prevented any significant increase in microvascular permeability, even when the manometer indicated pressures up to 45 cmH₂O. In contrast, when isolated excised lungs were ventilated with PIPs of only 15 cmH₂O for 1 hour (with overdistension), there was an 850% increase in microvascular permeability. This finding suggests that preterm infants with relatively healthy lungs and highly compliant chest walls may experience significant lung injury even at apparently low ventilator pressures. In addition, in the preterm lamb model, manual ventilation with as few as six very large breaths at birth may compromise the therapeutic effect of subsequent surfactant administration, leading to significant lung damage (Björklund et al., 1997; Dreyfuss and Saumon, 1998). Evidence that exposure to high tidal volumes in preterm human infants contributes to BPD comes from several sources. In particular, there is an association between hypocarbia and an increased incidence of BPD (Kraybill et al., 1989; Garland et al., 1995) as well the known association between lung overdistension and the occurrence of pneumothorax and pulmonary interstitial emphysema.

Multiple attempts have been made to decrease the incidence of BPD through improved ventilatory strategies (see also Chapter 45 on the principles of respiratory care). The use of high-frequency oscillatory ventilation (HFOV) as a primary mode of ventilation is one such strategy (Morierte et al., 2001; Courtney et al., 2002; Johnson et al., 2002). Although a statistically significant decrease in the incidence of BPD has been described in some studies, none of the studies using HFOV achieved large clinically relevant differences in outcome. A recent (2015) Cochrane Collaboration metaanalysis of randomized clinical trials of HFOV versus conventional ventilation found a modest effect of ventilation mode on the incidence of BPD (relative risk [RR] 0.86, 95% confidence interval [CI] 0.78–0.96) and on the incidence of BPD or death (Cools et al., 2015). However, heterogeneity among the study results was not explained by variation in ventilation strategies and failed to demonstrate efficacy of a strategy of lung recruitment with decreased need for supplemental oxygen. In fact, air leak syndromes were significantly increased with HFOV.

More recent advances in the delivery of synchronized ventilation for newborns have allowed for the introduction of volume-targeted ventilation (reviewed by Keszler, 2009). In contrast to pressure-limited ventilation, these strategies can limit the delivery of excessive tidal volumes in tiny preterm infants. However, the delivered tidal

volume is accurately assessed only in the “volume guarantee” mode, which measures and responds to the expiratory volume proximate to the airway. This is not available on all neonatal ventilators in common use. Although a metaanalysis did demonstrate decreased rates of BPD or death and decreased duration of intermittent positive pressure ventilation with volume-targeted ventilation, these effects were attenuated in the pragmatic studies where specific ventilators and the approach to triggering breaths were not matched in the two arms of the study, suggesting that other variables may have accounted for some of the differences seen (Wheeler et al., 2010). Episodes of hypocarbia were significantly decreased with volume-targeted ventilation. Generally, lung protection strategies have not explicitly been shown to decrease BPD. For example, a randomized trial to evaluate a minimal ventilation strategy (higher carbon dioxide partial pressure and lower pH targets compared with more standard targets) demonstrated no differences in the incidence of BPD or death (63% vs 68%) or other major morbidities (Carlo et al., 2002). However, in this study, the need for ventilatory support at 36 weeks’ PMA was significantly lower in the minimal ventilation group compared with the routine conventional ventilation treatment group (1% vs 16%). Thus the more permissive approach to assisted ventilation appears to influence the severity of BPD, although this approach alone may be insufficient to prevent the disorder.

Avery et al. (1987) published a descriptive review of treatment center differences in the incidence of BPD. Use of nasal CPAP immediately after delivery was associated with a much lower incidence of BPD at one center compared with the incidence at other centers. Subsequently, Van Marter et al. compared the practices and outcomes for neonatal units in Boston and at Columbia University and found that, overall, the incidence of BPD at Columbia was much lower, as was the use of mechanical ventilation, surfactant administration, indomethacin treatment, and sedation, while the use of nasal CPAP was higher (Van Marter et al., 2000). Infants on nasal CPAP at Columbia were supported with “bubble” CPAP, in which the end-expiratory pressure is created by an underwater seal. Bubble CPAP has been shown to deliver consistently higher intraprong pressures than ventilator-delivered CPAP set to the same end-expiratory pressure. However, variable-flow CPAP delivered by a dedicated device decreases work of breathing, in comparison with both bubble CPAP and ventilator-delivered CPAP (de Klerk and de Klerk, 2001; Pandit et al., 2001; Kahn et al., 2008).

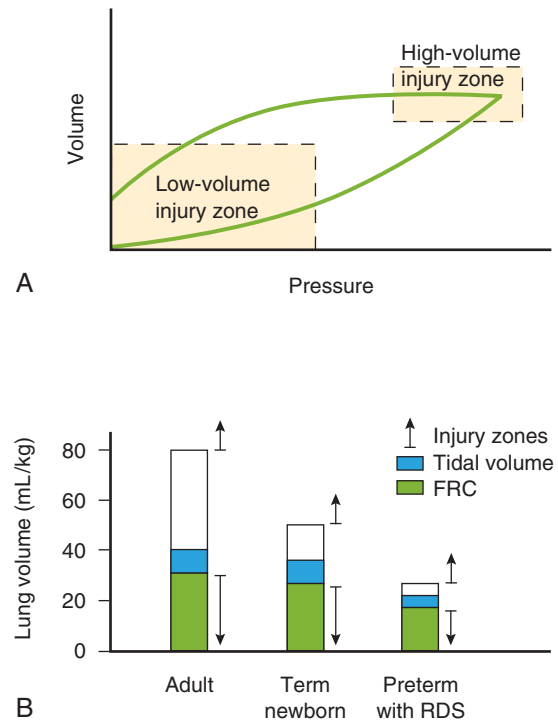

The need for early invasive ventilation identifies the least mature and sickest infants. In more recent reports, among extremely preterm infants that received mechanical ventilation despite a preferential strategy of nasal CPAP, those who were intubated were more depressed at delivery, with lower Apgar scores, lower GA and birth weight, more severe RDS by radiograph, and more impaired oxygenation (Ammari et al., 2005; Fuchs et al., 2011). Infants that required intubation were more likely to have a diagnosis of pneumothorax, severe intracranial hemorrhage, and BPD. However, a previous metaanalysis had demonstrated that infants with RDS who are intubated and rapidly extubated following exogenous surfactant after failing nasal CPAP (with inspired oxygen concentration ≤ 0.45) are less likely to have BPD (as assessed at 28 days), compared with infants who are intubated without a trial of CPAP (Stevens et al., 2007).

Beyond initial resuscitation and treatment of RDS, preterm newborns extubated to nasal CPAP are less likely to fail treatment than those supported without positive airway pressure, particularly when nasal CPAP is applied at greater than 5 cmH₂O pressure or

methylxanthines are administered (Davis and Henderson-Smart, 2003). However, this strategy has not been shown to decrease the incidence of BPD. There is no well-defined advantage to bubble CPAP over variable-flow CPAP for successful separation from mechanical ventilation (Gupta et al., 2009; Mazmanyan et al., 2015). Nasal CPAP, in comparison with humidified high-flow nasal cannula (as a strategy to apply continuous end-expiratory pressure), trends toward less treatment failure following tracheal extubation (RR 1.21, 95% CI 0.95–1.55), but there is no benefit of nasal CPAP for prevention of BPD (Wilkinson et al., 2016). Nasal intermittent positive pressure ventilation also does not provide an advantage over nasal CPAP for prevention of BPD following extubation or as a primary mode of support (Kirpalani et al., 2013).

The preferential application of nasal CPAP, as compared with early intubation and surfactant administration, to prevent BPD was studied in the COIN (Continuous Positive Airway Pressure or Intubation at Birth) and SUPPORT (Surfactant, Positive Pressure and Pulse Oximetry Randomized Trial) trials. Although both studies randomized extremely low GA newborns before birth to receive nasal CPAP or mechanical ventilation, the study designs differed. Infants eligible for COIN had to be spontaneously breathing at 5 minutes of age without previous intubation, whereas infants in the SUPPORT trial were managed from birth based on their treatment allocation (Morley et al., 2008; SUPPORT Study Group et al., 2010). Because informed consent was obtained prenatally, there were high rates of prenatal steroid exposure in these infants. There was not a significant decrease in the need for oxygen supplementation at 36 weeks' PMA in either of these trials. Furthermore, a greater number of infants assigned to the CPAP group were intubated: 46% in COIN and 83% in SUPPORT (with one-third of the CPAP group intubated in the delivery room). In both studies, there were fewer days of mechanical ventilation in the CPAP group, with a higher rate of pneumothorax in the CPAP group in the COIN trial and no difference in air leak in the SUPPORT trial. There were no increases in mortality or other comorbidities of prematurity.

The application of positive pressure in preterm infants is critical, as loss of functional residual capacity (FRC) with onset of generalized atelectasis also can be a major contributor to the development of BPD. In infants who are being ventilated below a normal FRC, repetitive opening and closing of lung units occur in the presence of maldistribution. This then leads to areas of significant overdistension. There is accumulating evidence from both animal and human newborns that the optimal use of PEEP is associated with a lower risk for BPD. Fig. 48.3 demonstrates the appearance of static pressure–volume curves for infants with either normal lungs or with RDS and also depicts the potential areas of lung injury from either high-volume ventilation or low-volume ventilation with atelectasis. Taken together, the literature supports a primary strategy of the application of nasal CPAP for extremely low gestation age newborns in the delivery room, with continuous distending pressure from birth to recruit lung and maintain FRC. However, there are probably subpopulations of infants who will still require intubation and surfactant administration, particularly those who are most immature and those who were not exposed to prenatal steroids. In a small single center study, the stable microbubble test from the gastric aspirate shortly after birth was used to quantify surfactant activity (Bhatia et al., 2013). The stable microbubble count significantly predicted CPAP failure and the need for intubation and exogenous surfactant administration with an area under the receiver operating characteristic curve of 0.80 (95% CI 0.70–0.90). For

• **Fig. 48.3** (A) Static pressure–volume curve indicating areas of lung injury from either high-volume ventilation or low-volume ventilation with atelectasis. (B) Lung volumes for a normal adult, a term newborn, and a preterm with respiratory distress syndrome. The low- and high-volume injury zones are indicated by arrows. The preterm lung is susceptible to injury with ventilation because of the small volume/kg between the two injury zones. FRC, Functional residual capacity; RDS, respiratory distress syndrome.

those infants that require intubation despite a strategy of preferential CPAP, the approach that would seem most likely to contribute to prevention of BPD is the use of an optimal PEEP to support a normal FRC combined with synchronized low-tidal-volume ventilation, with a goal of early extubation to nasal continuous distending airway pressure (CPAP or intermittent positive pressure).

Fluid Balance, Pulmonary Edema, and Patent Ductus Arteriosus

It is clear from animal studies (Bland et al., 2000) that abnormalities of lung fluid balance contribute to BPD. However, in a recent metaanalysis of studies of liberal versus strict fluid balance for prevention of BPD, the favorable effect of strict fluid balance was not significant (Bell and Acarregui, 2014). Notably, there were a limited number of extremely low GA newborns included in these trials. Patent ductus arteriosus (PDA) was decreased with fluid restriction, which is one mechanism by which fluid management may relate to BPD. In a retrospective study from the National Institute of Child Health and Human Development (NICHD) NRN of extremely preterm infants, higher fluid intake and lesser weight loss in the first 10 days of life were associated with increased odds of BPD or death (Oh et al., 2005). This study also showed that PDA was associated with increased odds of BPD or death, but this relationship is complex, as factors that predispose to symptomatic PDA are also associated with higher levels of respiratory support. In addition, the need for increased respiratory support usually prompts further evaluation for PDA (Weisz and McNamara,

2014). A post hoc analysis of a small randomized trial of prophylactic surgical PDA ligation conducted when the use of prenatal steroids was limited demonstrated increased BPD among surviving infants that underwent prophylactic ligation but no difference in the combined outcome of BPD or death (70% vs 66%) (Clyman et al., 2009). These data suggest that persistence of PDA did not affect the outcome of BPD, or those effects were offset by any adverse effects of surgical ligation. A more contemporary (1999–2009) time-series study of extremely low GA newborns who were managed with prophylactic indomethacin followed by an early, aggressive approach to PDA closure (including surgical ligation) versus a more conservative approach to closure did not demonstrate a difference in rates of BPD, despite a longer period of time with exposure to a moderate-to-large PDA in those infants with conservative management (Jhaveri et al., 2010). However, a more recent study (2006–2008) compared morbidities in infants with PDA from the Japanese and Canadian neonatal networks (Isayama et al., 2015). In Japan, the approach to PDA is one of active surveillance and treatment, whereas in Canada, it is one of selective evaluation and treatment. Infants with PDA in Japan demonstrated decreased odds of BPD. Interestingly, rates of prenatal glucocorticoid exposure were lower in the Japanese cohort than in the Canadian cohort, regardless of PDA status. Two recent studies demonstrated that a more hemodynamically important PDA (by echocardiographic markers) is independently associated with increased odds of BPD (El-Khuffash et al., 2015; Schena et al., 2015). In a multivariate analysis, El-Khuffash et al. further demonstrated that surgical ligation was not significantly associated with development of BPD, after controlling for PDA severity.

Pulmonary Vascular Abnormalities

Prospective studies evaluating early echocardiographic findings in extremely preterm newborns have demonstrated that early changes (7–14 days) on echocardiogram consistent with elevated pulmonary arterial pressure are associated with the later development of BPD (Mirza et al., 2014; Mourani et al., 2015). This right-heart pressure elevation was also associated with increased need for mechanical ventilation. Vascular changes in the placenta are also associated with increased odds of BPD, as well as BPD complicated by the clinical diagnosis of pulmonary hypertension, based on echocardiographic findings consistent with elevated pulmonary arterial pressure (Mestan et al., 2014). Other work implicating the fetal environment in the pulmonary vascular development demonstrated that among extremely low GA newborns with BPD, those with less robust fetal growth (lowest quartile of birth weight percentile for GA) were more likely to have a clinical diagnosis of pulmonary hypertension, after adjustment for other perinatal factors, along with more severe BPD (Check et al., 2013). Thus intrauterine and early neonatal differences in vascular growth and development may result in early signs of elevated pulmonary artery pressure, pulmonary vascular disease, and ongoing impairment of vascular development, with greater likelihood of BPD. Interestingly, in the largest prospective cohort of echocardiographic surveillance for pulmonary hypertension published to date, PDA on the day 7 echocardiogram was associated with both severity of later BPD and elevated right-heart pressure estimates (Mourani et al., 2015). In some cases, this increase in pressure may be due to a hemodynamically important PDA with substantial left-to-right flow, further implicating the interaction between the presence of the PDA and the ongoing need for mechanical ventilation in alveolar and microvascular growth and development.

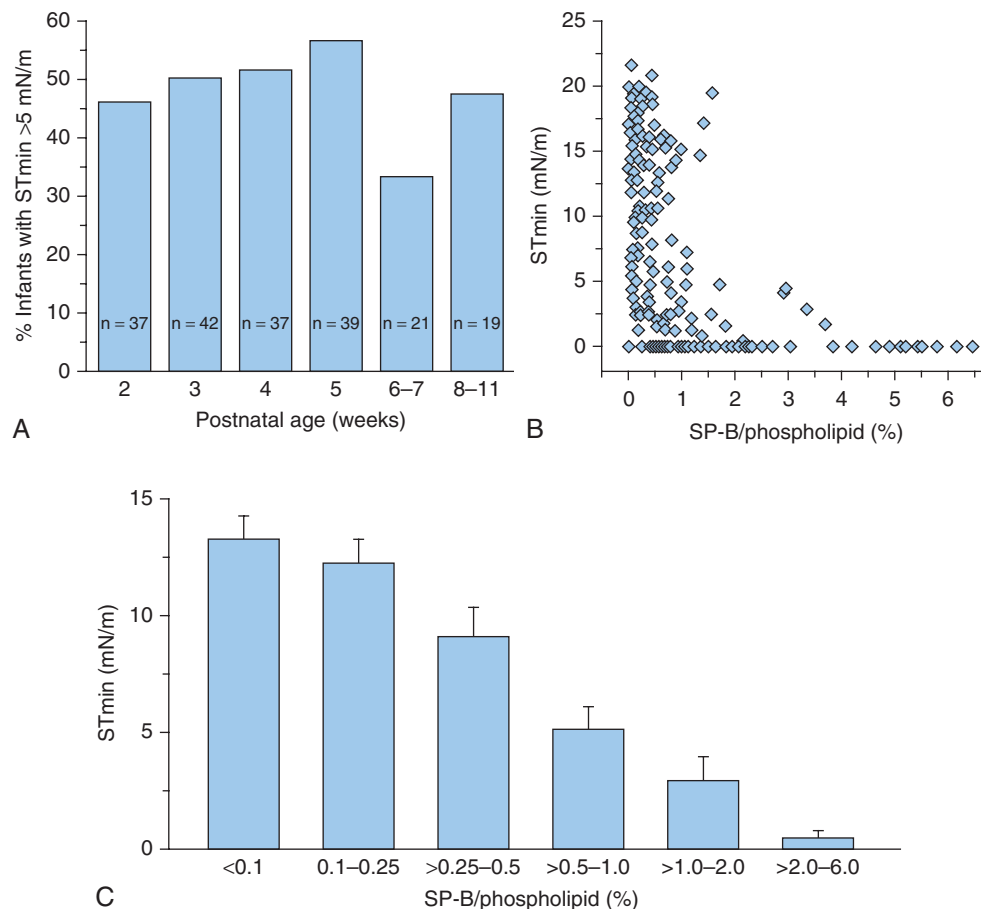

Inadequate Nutrition

Further data supporting the role of impaired fetal growth in the development of BPD come from multiple larger epidemiologic studies (Bose et al., 2009; Durrmeyer et al., 2012; Torchin et al., 2016). Although these studies applied different reference curves and different thresholds for classification of intrauterine growth restriction, the consistent findings from these and other studies suggest that there is a biologic mechanism to this relationship. It is likely that the effects of growth restriction on pulmonary vascular development are some combination of direct placental or trans-placental effects of maternal vascular disorders and the more global effects of nutritional deprivation on lung and vascular development, as newborns who are products of these complicated pregnancies that are also growth restricted have the highest risk of later development of BPD (Durrmeyer et al., 2012; Torchin et al., 2016). Regardless, the effects of the aforementioned etiologic factors and others are intensified by the inability to provide adequate neonatal nutritional support for extremely preterm newborns, particularly those who are acutely ill (Martin et al., 2009). These infants have delayed initiation and advancement of enteral feeds, inadequate parenteral nutrition because of restricted fluid intake, and a catabolic state secondary to illness and increased work of breathing. Martin et al. described growth failure in 75% of extremely low GA newborns at 28 days old (Martin et al., 2009). Growth failure at 36 weeks' PMA and beyond is common among extremely preterm infants with BPD. However, earlier enteral feeding and earlier and greater amino acid administration result in lower rates of growth failure (Theile et al., 2012; Natarajan et al., 2014; Poindexter et al., 2015). Restricted nutritional intake results in decreased alveolar number with alveolar simplification and dysregulated lung development in animal models of alveolarization (Massaro et al., 2004; Joss-Moore et al., 2016). These differences can be reversed by normalizing nutritional intake. In addition, preterm infants have vitamin deficiencies (e.g., vitamin A, vitamin E) associated with disruption of alveolar formation and diminished antioxidant activity (Abdel Ghany et al., 2016). Poor nutrition also leads to increased susceptibility to infection, which leads in turn to a further cycle of impaired defense against injury.

Surfactant Dysfunction

Surfactant dysfunction is common among extremely low birth weight infants that remain intubated beyond the first week after birth (Fig. 48.4) (Merrill et al., 2004, 2011; Keller et al., 2012). In addition, episodes of infection or respiratory deterioration (sustained increase in inspired oxygen concentration and/or mean airway pressure) have been associated with increasing surfactant dysfunction. The surfactant content of the surfactant proteins (SP) B and C is tightly correlated with surfactant function in preterm infants, with lower SP levels correlated with higher surface tension. This is particularly true of SP-B, which increases acutely with SP-B-containing exogenous surfactants and which is downregulated by TGF- β (McDevitt et al., 2007; Keller et al., 2012); other studies in animals and humans have demonstrated decreased SP content or expression following exposure to oxygen and cytokines.

Later administration of animal-based surfactants as rescue for clinical decompensation in preterm newborns has been evaluated, with a short-term decrease in ventilator settings following surfactant administration (Pandit et al., 1995; Katz and Klein, 2006; Bissinger et al., 2008). An additional study in persistently ventilated preterm newborns showed similar effects (Merrill et al., 2011). Pilot

• **Fig. 48.4** Surfactant Dysfunction in Ventilated Preterm Infants. (A) Prevalence of surfactant dysfunction (minimum surface tension [STmin] > 5 mN/m) during weeks 2 to 11 of life in ventilated preterm infants. Dysfunction of pulmonary surfactant in chronically ventilated premature infants. *Pediatr Res*. 2004;56:918–926.)

randomized studies of SP-B (or an analogue)–containing surfactants in preterm infants persistently ventilated at 3 to 14 days have also demonstrated transient decreases in ventilator support compared with controls but no effect on the prevention of BPD or death at 36 weeks (lucinactant, Discovery Laboratories, Inc., Warrington, PA; calfactant, Ony Inc., Amherst, NY; poractant alfa, Chiesi USA, Inc., Cary, NC) (Laughon et al., 2009b; Keller et al., 2012; Hascoët et al., 2016). The large multicenter Trial of Late Surfactant (TOLSURF) randomized extremely low GA newborns who remained intubated at 7 to 14 days to calfactant (up to 5 doses) in combination with iNO versus iNO alone. Although there was no effect on survival without BPD at 36 weeks' PMA, there was a trend toward an increase in this outcome assessed at 40 weeks' PMA, and late surfactant administration was safe and well-tolerated (Ballard et al., 2016).

Adrenal Insufficiency

Preterm infants may have developmental immaturity of the hypothalamic–pituitary–adrenal axis, with an increased risk of BPD secondary to inadequate responses to inflammatory lung injury (Watterberg and Scott, 1995; Watterberg et al., 1996). Banks

et al. reported, however, in a study of cortisol levels in 314 preterm infants, that even the earliest gestation infants (24–25 weeks) have an increase in cortisol after delivery and that levels were not associated with GA (Fig. 48.5) (Banks et al., 2001). Using the Clinical Risk Index for Babies score to adjust for clinical risk factors, low cortisol at 3 to 7 days of age contributed minimally to increasing the risk for BPD, and there was no correlation at 14 to 28 days. A subsequent cohort of infants from the PROPHET (Prophylaxis of Early Adrenal Insufficiency to Prevent Bronchopulmonary Dysplasia) study demonstrated no relationship between cortisol levels in the first week and BPD, although higher cortisol levels were associated with increasing incidence of other acute and chronic morbidities (Aucott et al., 2008, 2010). Three randomized studies, including PROPHET, investigated “physiologic replacement” hydrocortisone dosing (total dose of 8.5–13.5 mg/kg over 10–15 days) for the prevention of BPD in extremely preterm newborns (Watterberg et al., 2004; Peltoniemi et al., 2005; Baud et al., 2016). Two of the studies were terminated prematurely due to increased rates of intestinal perforation in the hydrocortisone-treated group. No benefit on the primary outcome of survival without BPD in either study was seen (Watterberg et al., 2004; Peltoniemi et al., 2005).

• **Fig. 48.5** Plasma Cortisol Concentrations in Premature Infants During the First 4 Weeks of Life. Data are mean levels stratified by gestational age: 24–25 weeks ($n = 81$), 26–27 weeks ($n = 98$), and 28–32 weeks ($n = 135$).

The most recent study differed, as the cumulative hydrocortisone dose was lower than in the other studies, and it enrolled only inborn infants, with no requirement for mechanical ventilation (Baud et al., 2016). Other differences included limitations on use of ibuprofen and open-label glucocorticoids. This study did show a benefit of increased survival without BPD (odds ratio 1.48, 95% CI 1.02–2.16), with fewer infants intubated on mechanical ventilation at 7 days and with no increase in adverse events in the intervention group. Although the PROPHET study demonstrated a significant interaction between clinical chorioamnionitis and hydrocortisone treatment (with the infants exposed to the anti-inflammatory steroid more likely to survive without BPD), other studies have not demonstrated this differential effect. Of interest is the fact that formation of alveolar septae in animals, a critical step in alveogenesis, occurs during a period of low serum glucocorticoid levels. Furthermore, dexamethasone administered to newborn rodents results in persistent impaired septation and alveogenesis (Massaro and Massaro, 2000). Thus there is not consistent evidence that adrenal insufficiency contributes to BPD in the general population of at-risk premature infants.

Inhibition of Normal Lung Development and Vascular Development

Some of the contributing factors described above directly impair normal formation of secondary septae and therefore microvascular development and alveolarization. Others arrest alveolarization by as-yet unknown processes that also involve structural differences in the extracellular matrix. These insults, occurring during the saccular stage of lung development, include inflammation and cytokine overexpression, dexamethasone exposure, hyperoxia, hypoxia, and inadequate nutrition (Albertine et al., 1999; Jobe, 1999; Massaro and Massaro, 2000; Massaro et al., 2004). Fig. 48.6 shows imaging and pathology from an infant who died from BPD complicated by pulmonary hypertension.

Preventive Factors

The Bronchopulmonary Dysplasia Group, convened to identify strategies for investigation of therapies to prevent or treat BPD, proposed classes of drugs to prevent or treat evolving (at 7 to 14 days) BPD (Walsh et al., 2006). These included antiinflammatory

agents such as prenatal and postnatal corticosteroids (PNCS) and other small molecules, antioxidants, iNO, late surfactant replacement, and improved vitamin A preparations. Additional approaches that have been proposed and evaluated include alternative ventilation strategies and the primary use of nasal CPAP. Box 48.2 lists both nonpharmacologic and pharmacologic approaches to preventing or decreasing severity of BPD, with these approaches and others discussed further in this section.

Prenatal Steroids

Numerous clinical studies and several large metaanalyses have demonstrated that prenatal glucocorticoids administered to women at high risk for premature delivery result in decreased mortality and morbidity associated with prematurity, including RDS, intraventricular hemorrhage, and necrotizing enterocolitis (NEC) (Roberts and Dalziel, 2006). However, the benefit of prenatal glucocorticoids for prevention of BPD among survivors is not consistent. The nonsignificant effect of prenatal steroids on BPD may be due to the increased survival of higher risk, less mature preterm infants following prenatal glucocorticoid exposure.

Surfactant Replacement Therapy

Surfactant replacement therapy is clearly associated with decreased severity of RDS and its associated mortality. Although survivors do not have a decreased incidence of BPD, a decrease in BPD or death was demonstrated in a recent metaanalyses (Seger and Soll, 2009). Investigations of late surfactant replacement, during a period of secondary surfactant dysfunction (Merrill et al., 2004), for prevention of BPD in those infants that continue to require mechanical ventilation after the first week of life, have been undertaken. Several pilot randomized studies and one larger trial evaluated the effects of late surfactant replacement on the respiratory status of extremely preterm infants requiring mechanical ventilation from days 3 to 14 (Laughon et al., 2009b; Keller et al., 2012; Ballard et al., 2016; Hascoët et al., 2016). In addition to improved surfactant function and increased levels of SP-B following late surfactant replacement in these infants at high risk for surfactant dysfunction, these exogenous surfactant preparations (calfactant, poractant alfa) have antioxidant activity, which may mitigate the

• **Fig. 48.6** Pulmonary Imaging and Pathology in a Former Preterm Infant With a History of Oligohydramnios, With Severe Bronchopulmonary Dysplasia and Pulmonary Hypertension at 44 Weeks' Postmenstrual Age. (A) Computed tomography scan with contrast demonstrating patchy consolidation and mosaic perfusion, consistent with poor ventilation–perfusion matching. (B) Postmortem pathology demonstrates alveolar enlargement, consistent with alveolar simplification. (C) On higher magnification, pulmonary vascular changes indicative of pulmonary hypertension are present. (D) Patchy septal thickening is seen on higher magnification.

effects of ongoing lung inflammation and oxidative stress for these persistently intubated infants (Dani et al., 2009; Merrill et al., 2011; Keller et al., 2012). Despite transient (up to 24 hours) decreases in level of respiratory support, late surfactant failed to significantly increase survival without BPD at 36 weeks' PMA in all of these studies (Laughon et al., 2009b; Keller et al., 2012; Ballard et al., 2016; Hascoët et al., 2016). However, the two studies that evaluated later outcomes (at 9–12 months corrected age) suggested that late surfactant decreased respiratory resource utilization following neonatal hospital discharge (Hascoët et al., 2016; Keller et al., 2016b).

Gentle Ventilation and Nasal Continuous Positive Airway Pressure

As described previously, volutrauma as well as atelectasis contributes directly to lung damage and the release of cytokines, which further the cycle of damage. With respect to respiratory support strategies for extremely preterm newborns, the body of evidence suggests that a primary strategy of nasal continuous distending airway pressure (as CPAP, biphasic CPAP, or intermittent positive pressure ventilation), expeditious transition to nasal continuous distending airway pressure for those infants who require early surfactant

replacement therapy, and patient-triggered low-volume ventilation for those infants who are unable to be extubated are safe approaches to respiratory support that may decrease the incidence of BPD. These studies have been done under stringent protocols for respiratory management based on clinical status, level of respiratory support, and blood gas parameters, which is probably important for both potential risks and benefit of these approaches. Regardless, the current evidence does not support a primary strategy of high-frequency ventilation or the use of high-flow nasal cannula in lieu of nasal CPAP in extremely premature infants. Furthermore, there is no evidence to support a target oxygen saturation of 85%–89% (vs 91%–95%) to decrease supplemental oxygen exposure from birth for prevention of BPD—mortality may be increased in subgroups of preterm newborns, while rates of BPD are not significantly decreased. However, there are not currently adequate data to otherwise identify an appropriate oxygen saturation target; higher oxygen saturation targets are associated with increased rates of severe retinopathy of prematurity, and in addition to mortality, rates of NEC may be increased with lower oxygen saturation targets (Manja et al., 2015).

Vitamin A

Vitamin A is an essential nutrient for maintaining respiratory tract epithelial cells and also is stored in the septal cells of the alveoli involved in alveolar septation. Compelling animal data also support the need for vitamin A (see Fig. 48.6) (Albertine et al., 1999). Because vitamin A is accumulated predominantly in the third trimester, preterm infants have deficient liver stores of this vitamin (Zachman, 1989). These infants, who often are unable to tolerate enteral feedings, are at particular risk for vitamin A deficiency since vitamin A added to parenteral nutrition solutions is degraded by light and can adhere to the intravenous tubing, making it largely inaccessible.

A number of clinical trials have investigated whether supplementation with vitamin A, typically by intramuscular injections, would result in a decrease in BPD. The largest study to date, by the NICHD-funded NRN, also used one of the higher doses that has been studied and demonstrated a decrease in BPD or death at 36 weeks following treatment with vitamin A (55% vs 62%) (Tyson et al., 1999). A recent metaanalysis of all published trials revealed that vitamin A supplementation was associated with a modest reduction in death or BPD at 36 weeks, which was of borderline statistical—and perhaps clinical—significance (RR 0.91, 95% CI 0.82–1.00, number needed to treat [NNT] 17) (Darlow and Graham, 2011). Vitamin A is well tolerated, and there are no safety issues, although it does involve repeated intramuscular injections. A recent report found that costs associated with intramuscular vitamin A administration for prevention of BPD were favorable if multiple infants were being treated concurrently with doses drawn from the same vial but substantially higher when vials were used for single dose administration (Couroucli et al., 2016).

Interestingly, survey data have shown that a minority of centers routinely administer vitamin A supplementation to at-risk infants, with inadequate evidence or lack of substantial effect cited as the rationale for lack of supplementation (Ambalavanan et al., 2004). Furthermore, data analyzed from before and during a period of a national shortage of the vitamin A preparation (2010–2012) demonstrated a large fall in vitamin A administration in at-risk infants from greater than 30% to less than 5% of the target population (Tolia et al., 2014). However, there was no change in the rate

of death of BPD for these at-risk infants over these two epochs, data which were further supported in multivariate analysis controlling for other risk factors for BPD. Thus the efficacy of vitamin A for prevention of BPD may be lacking in the setting of contemporary strategies for the care of the extremely preterm newborn (Gawronski and Gawronski, 2016).

Systemic Postnatal Corticosteroids

Preterm infants given PNCS demonstrate some decreased inflammatory markers and suppression of cytokine-mediated inflammatory reactions in their tracheal aspirates. Other than direct antiinflammatory effects, numerous theoretical reasons have been advanced regarding why postnatal administration of steroids might decrease the incidence of BPD, including the potential for increased surfactant synthesis, enhanced β -adrenergic activity, increased antioxidant production, stabilization of cell and lysosomal membranes, and inhibition of prostaglandin and leukotriene synthesis (Watterberg et al., 1999). These potential benefits are balanced against the knowledge that dexamethasone exposure results in persistent decreases in alveolar numbers in animal models and irreversible effects on brain development (Massaro and Massaro, 2000; Kreider et al., 2006; Heine and Rowitch, 2009; Bhatt et al., 2013).

Clinical trials have demonstrated acute improvements in dynamic compliance and pulmonary resistance following treatment with PNCS, although small follow-up studies have demonstrated no differences in reported respiratory morbidity despite a trend toward improved pulmonary function in children greater than 5 years of age treated with dexamethasone (Nixon et al., 2007; Doyle et al., 2014b). Many have separated out the effects of early (≤ 7 days) versus late (> 7 days) initiation of PNCS predominantly because of differences in adverse side-effect profiles based on the timing of exposure. Based on two recent metaanalyses (Doyle et al., 2014a, 2014b), postnatal dexamethasone has similar beneficial effects on death or BPD at 36 weeks (RR 0.76–0.89, 95% CI, 0.68–0.94), decreased need for mechanical ventilation at 3 to 28 weeks after initiation of therapy, and no significant effect on survival to hospital discharge regardless of the timing of drug initiation. Aggregated studies of hydrocortisone administered in the first week of life demonstrate no effects on mortality or BPD, although this analysis was prior to the results of the most recent trial (Baud et al., 2016).

Major concerns exist regarding both short-term and long-term side effects of PNCS, including systemic hypertension, hyperglycemia and glycosuria, hypertrophic cardiomyopathy, adrenal suppression, and decreased growth. Early administration of PNCS in the first week after birth carries an increased risk of gastrointestinal perforation for both dexamethasone and hydrocortisone (RR 1.81, 95% CI 1.33–2.48) (Doyle et al., 2014a). This effect may be associated with concurrent administration of indomethacin (Watterberg et al., 2004). Gastrointestinal hemorrhage is also significantly increased (RR 1.87, 95% CI 1.35–2.58) with early dexamethasone. Individual studies have reported an increased risk of later cerebral palsy (CP) in children treated early with dexamethasone (Yeh et al., 1998; Shinwell et al., 2000). The metaanalyses support this concern for dexamethasone (with no effect seen with hydrocortisone); the relationship was not statistically significant when treatment is initiated after 7 days of age (Doyle et al., 2014a, 2014b).

In recognition of these accumulated findings, a statement from the American Academy of Pediatrics revised a previous recommendation against any routine use of postnatal dexamethasone in preterm infants (Watterberg et al., 2010). The current statement

distinguishes between high-dose dexamethasone administration, which is not recommended, and low-dose dexamethasone administration, where current evidence of benefit versus risk is lacking. Additional recent assessments illustrate overlap between the NNT (prevent BPD) and the number needed to harm (abnormal neurologic outcome, including CP) for early dexamethasone treatment, which may be related both to the cumulative dose of the medication and an individual infant's risk for BPD (Schmidt et al., 2008; Onland et al., 2009; Doyle et al., 2014c; Jensen et al., 2015). A large cohort study demonstrated a dose-dependent increased risk of death or neurodevelopmental impairment (NDI) at 18 to 22 months corrected age, regardless of PMA at the time of dexamethasone exposure (Wilson-Costello et al., 2009). However, the excess risk caused by PNCS exposure was decreased for those infants at highest risk for BPD. Similarly, in a metaanalysis of randomized trials, Doyle et al. (2014c) demonstrated that the excess risk of CP caused by dexamethasone exposure was obliterated with increasing rates of BPD in the control group. Essentially, at an underlying BPD incidence of 46% (95% CI 33%–60%), there was no excess risk of the outcome of CP or death and a diminishing risk with higher rates of BPD. With respect to dose, a separate metaanalysis suggested that higher cumulative dexamethasone dose was inversely associated with rates of BPD, for infants with treatment initiated in the first 2 weeks of life (Onland et al., 2009). With respect to NDI, earlier treatment initiation had an inverse relationship to risk of NDI. However, for later treatment, the relationship was reversed, with higher doses associated with higher risk of NDI, although this relationship was not significant. The interpretation of the cumulative data therefore is challenging, as infants who are studied outside of a randomized trial may not have appropriate controls, because of the bias regarding who is treated clinically, whereas open-label use of PNCS during clinical trials alters the ability to assess both beneficial and adverse effects of treatment (Onland et al., 2010).

An ongoing study aims to address the issue of safety and efficacy of later treatment with hydrocortisone (The Hydrocortisone for BPD study, NCT01353313). In this study, extremely preterm newborns who continue to require mechanical ventilation at 14 to 28 days are randomized to hydrocortisone or placebo. In addition to the later timing of intervention, this study protocol entails a higher dose of hydrocortisone than had been previously administered in randomized trials (18 mg/kg over 10 days). Follow-up of growth and development at 22 to 26 months corrected age is also being undertaken, to fully understand both benefits and risks of this intervention. However, it is also possible that this window of intervention will be too late to “prevent” BPD, as the underpinnings of the disorder may already be established. For instance, in the NO CLD study, infants treated with iNO initiated at 7 to 14 days had decreased BPD rates, whereas those with the drug initiated at 15 to 21 days had no effect (Ballard et al., 2006; Ballard, 2007). A recent secondary analysis from TOLSURF of cumulative supplemental oxygen exposure over the first 28 days also demonstrated that there was no additional predictive value for this index beyond 14 days (Wai et al., 2016).

Overall, the data suggest that the subset of infants at highest risk for BPD may benefit from dexamethasone. Although the optimal timing of this intervention is not clear, it seems prudent to avoid the concurrent administration of PNCS and inhibitors of prostaglandin synthesis (e.g., indomethacin, ibuprofen) early in the postnatal course. Regardless, there are insufficient data to support the use of any other systemic steroid at this point in time.

Inhaled/Instilled Corticosteroids

Because of concern for systemic effects of PNCS, there has been continued interest in local delivery of steroids to the lung. Although inhaled steroids initiated in the first 2 weeks have been studied for prevention of BPD, there were not significant improvements in either immediate or later respiratory status with this intervention, including no significant effect on death or BPD in a metaanalysis (Shah et al., 2012). There was a trend toward decreased systemic PNCS use in these infants and no increase in rates of the acute side effects seen with systemic PNCS administration (compared to placebo). A recent study of inhaled budesonide (delivered by metered-dose inhaler with spacer) in extremely low GA newborns receiving positive pressure in the first day after birth had a borderline significant effect on death or BPD (RR 0.86, 95% CI 0.75–1.00) (Bassler et al., 2015). Infants were treated until 32 weeks' PMA or off positive pressure support (whichever came first) with an average of 33.9 ± 15.9 days for infants in the budesonide group. Although BPD was decreased in survivors in the budesonide-treated group, mortality was nonsignificantly increased. There were fewer infants reintubated in the intervention group, fewer undergoing PDA ligation, and no increase in rates of potential side effects or growth parameters over the first 28 days. These data are interesting with respect to the pulmonary effects, but the higher mortality in the treated group raises concerns for systemic absorption of budesonide, as the target tissue for inhaled drugs is the airway, but proximal deposition of drug also occurs.

Instillation of budesonide by suspending it in surfactant provides another method of budesonide delivery to the lung, which may more selectively reach the lung parenchyma. In fetal lung explants, incubation with budesonide suppresses inflammatory markers by 90% 12 hours after addition of budesonide (Barrette et al., 2016). This effect was unchanged after budesonide was suspended in calfactant, and surface tension of calfactant was minimally affected. Budesonide suspended in calfactant administered intratracheally to preterm lambs demonstrates a plasma half-life of 4.76 ± 1.79 hours, with nonmetabolized budesonide and budesonide palmitate (fatty acid ester), but not the primary metabolite of budesonide, present in lung tissue (Roberts et al., 2016). Neither budesonide nor its metabolites were found in brain tissue, suggesting that the budesonide absorbed systemically did not cross the blood–brain barrier. A pilot study of budesonide (0.25 mg/kg) with Surfactant (beractant, Abbott Laboratories, Columbus, OH) compared to Surfactant alone for treatment of RDS in very low birth weight preterm infants similarly demonstrated a plasma half-life of 4.13 hours with only approximately 4% of the budesonide dose calculated to enter the systemic circulation, based on drug and metabolite levels (Yeh et al., 2008). In this study, respiratory status improved over 1 to 3 days, and treated infants were extubated earlier, compared with infants treated with beractant alone, without an increase in acute adverse effects. There was also a significantly lower rate of death or BPD. A larger multicenter study extended these findings, demonstrating decreased death or BPD (RR 0.58, 95% CI 0.44–0.77), with both lower mortality and BPD rates in the budesonide-treated group and no increase in comorbidities of prematurity (Yeh et al., 2016). Furthermore, tracheal aspirate inflammatory markers were lower in treated infants than controls: IL-1 and IL-6 were decreased at 12 hours after the intervention, and IL-8 was decreased for up to 8 days following the intervention. Neurodevelopmental follow-up from these trials did not suggest an increase in NDI at 2 to 3 years corrected age, although these studies were underpowered to detect significant differences (Kuo

et al., 2010; Yeh et al., 2016). Thus instilled budesonide may achieve local glucocorticoid (including antiinflammatory) effects on the lung, without adverse systemic and neurodevelopmental consequences. However, the appropriate dose and target population for a definitive study to prevent BPD remain to be determined, as the dose administered by Yeh et al. was substantial.

Antioxidant Therapy

Some evidence in the baboon model of BPD indicates that a catalytic antioxidant, metalloporphyrin, can protect against hyperoxia-induced lung injury (Chang et al., 2003). Superoxide dismutase is a naturally occurring enzyme that protects against oxygen free radical injury. Human studies have suggested that administration of intratracheal rhSOD is well-tolerated and might have beneficial effects on the lung; a randomized trial of rhSOD, which was stopped prematurely because of lack of efficacy for prevention of BPD, demonstrated an improvement in respiratory morbidity at 1 year corrected age (Davis et al., 2003). Other therapies proposed to prevent BPD may provide or augment antioxidant activity (e.g., mesenchymal stem cell transplant, exogenous surfactant replacement), which is one potential mechanism by which they might have an effect on the development of BPD.

Inhaled Nitric Oxide

Prolonged iNO from birth in animal models of BPD improves endogenous surfactant function as well as lung growth, angiogenesis, and alveogenesis (Bland et al., 2005; McCurnin et al., 2005). In addition, recovery from injury using iNO attenuates the impaired alveolar and microvascular development associated with prolonged hyperoxia exposure in the rodent (Lin et al., 2005). Prematurity in the baboon, and presumably in the human, is associated with developmentally deficient endogenous nitric oxide production (Shaul et al., 2002). Accordingly, iNO following preterm birth may be viewed as replacement therapy. Multiple studies of iNO initiated in the first 72 hours after birth, for prevention of BPD in ventilated preterm infants, have been conducted—with results showing variable efficacy (Kinsella et al., 1999, 2006; Schreiber et al., 2003; Van Meurs et al., 2005; Mercier et al., 2010). Safety concerns were raised in the single study that enrolled sicker infants with a higher baseline oxygenation index, because of increased severe intracranial hemorrhage (Van Meurs et al., 2005), but improved neurologic outcomes were found in less ill newborns (Mestan et al., 2005; Kinsella et al., 2006). These studies treated infants for variable duration, up to 21 days, with doses of 5–10 ppm. Kinsella et al. (2014) also studied preterm infants who were not intubated, but required respiratory support in the first 3 days, and found no benefit of iNO for prevention of BPD.

In the NO CLD Trial, which enrolled ventilated infants 500 to 1250 grams at 7 to 21 days who had evolving BPD, infants received at least 24 days of iNO therapy, with a dose of 10–20 ppm for at least 10 days (Ballard et al., 2006; Ballard, 2007) (Fig. 48.7 shows a comparison of dosing and duration of trials). In this study, the rate of survival without BPD at 36 weeks significantly increased from 37% to 44%, and fewer days of ventilation resulted in a relative cost savings with iNO (Zupancic et al., 2009). There was a significant interaction of treatment with the age at study entry, with infants that entered earlier (at 7–14 days) being more likely to benefit (increase in survival without BPD from 27% to 49% (NNT = 4). The benefit of treatment persisted at 40 weeks' PMA, with iNO-treated infants more likely to be discharged or hospitalized

• **Fig. 48.7** Summary of Large Trials of Inhaled Nitric Oxide for Prevention of Bronchopulmonary Dysplasia by Day of Life Versus Inhaled Nitric Oxide Dose. Duration of treatment and total nitric oxide dose are depicted. iNO, Inhaled nitric oxide; ppm, parts per million. (Adapted from Truog WE. Inhaled nitric oxide for the prevention of bronchopulmonary dysplasia. *Expert Opin Pharmacother.* 2007;8:1505–1513.)

without respiratory support, and both the earlier and later (15–21 days) treated groups had evidence of benefit at that point in time (Keller et al., 2009). Furthermore, pulmonary morbidity at 1 year was decreased in the iNO-treated group (fewer infants requiring supplemental oxygen and decreased use of bronchodilators, diuretics, and inhaled and systemic steroids). All subgroups of treated infants benefited (Hibbs et al., 2008). iNO therapy initiated at 7 to 21 days was also safe. There was no difference in the rate of comorbidities of prematurity between the treatment and control groups and no difference in the rate of neurodevelopmental impairment by treatment group at 2 years corrected age (Walsh et al., 2010).

A systematic review of studies in ventilated infants demonstrated an overall modest benefit of iNO that was not statistically significant (RR 0.90–0.94, 95% CI 0.80–1.02) (Barrington and Finer, 2010). However, an individual-patient data (IPD) metaanalysis did demonstrate a modification of the iNO effect by initial iNO dose: trials with a starting dose greater than 5 ppm demonstrated significant benefit (RR 0.83, 95% CI 0.74–0.95), a response which was not seen in trials with a starting dose greater than 5 ppm ($P = .02$ for interaction) (Askie et al., 2011). A more recent IPV, including newer data from an as-yet unpublished study conducted by the company that manufactures iNO (INOMax, Mallinckrodt Inc., St. Louis, MO) demonstrated that, in studies of ventilated infants with iNO starting dose of greater than 5 ppm, infants of black mothers were more likely to respond to iNO than other infants ($P = .01$ for interaction) (Ballard et al., 2016). Another potential predictor of iNO response is low endogenous nitric oxide production before therapy. The lowest quartile of nitric oxide metabolites in tracheal aspirate fluid at study entry was associated with the highest rate of survival without BPD in the NO CLD study (Posenchev et al., 2010). Thus it may be that there are subpopulations of infants that are more likely to respond to iNO, when given at an effective dose.

Caffeine

Schmidt et al. reported that the administration of caffeine, initiated in the first 10 days to facilitate extubation, or to prevent or treat apnea of prematurity, decreased the risk of BPD at 36 weeks from

47% to 36% in infants 500–1250 grams in the Caffeine for Apnea of Prematurity (CAP) Trial (Schmidt et al., 2006). Infants treated with caffeine were permanently weaned off mechanical ventilation, positive airway pressure, and supplemental oxygen approximately 1 week earlier, with less exposure to PNCS and lower rates of treatment for PDA. Caffeine was discontinued at a median of 34 weeks' PMA. There was a transient decrease in weight gain in treated infants, but no other substantial adverse effects were seen. A post hoc analysis of subgroups of infants demonstrated similar effects of caffeine on prevention of BPD, regardless of the indication for initiation of therapy and whether infants were on noninvasive or invasive positive pressure support at the initiation of therapy (Davis et al., 2010). Infants randomized early (<3 days) were more likely to benefit than those randomized at 4 to 10 days. Furthermore, caffeine-treated infants had a significantly higher rate of survival without NDI (40% vs 46%) at 18 to 21 months corrected age, with lower rates of CP (Schmidt et al., 2007). At 5 years, there was no statistically significant improvement in rates of death or disability in the caffeine-treated group, and motor outcomes were significantly better (Schmidt et al., 2012).

An economic analysis has demonstrated that caffeine therapy was cost-effective, as it resulted in lower costs and better outcomes (Dukhovny et al., 2011), and two retrospective studies from cohort data in the United States and Canada showed decreased rates of BPD, with a trend toward improved neuroimaging outcomes with early initiation of caffeine (Dobson et al., 2014; Lodha et al., 2015). Although the mechanism of the effect of caffeine on BPD is not clear, small studies demonstrated that caffeine improves diaphragmatic excursion and neural control of breathing, with increased tidal volume, which provides good rationale for its use and efficacy in extremely preterm infants with respiratory system dysfunction (Bancalari, 2006; Kraaijenga et al., 2015; Parikka et al., 2015).

Clinical Course and Treatment

As mentioned earlier, the classic BPD described by Northway et al. is now rare with the advent of prenatal steroids, exogenous surfactant, and ventilators and ventilator strategies better suited for newborn infants. Thus here we address only the clinical course of the new BPD, primarily affecting infants who are extremely low birth weight/low GA (<1000 grams and 28 weeks') that require prolonged ventilator support because of underlying lung disease complicated by apnea or poor respiratory effort. Following the use of prenatal steroids and postnatal surfactant, these infants may initially require relatively low concentrations of oxygen with fairly mild lung disease. However, their clinical course is often complicated by infection, systemic hypotension and PDA, NEC or other intestinal complications, difficulty establishing or maintaining enteral feeds, and an overall proinflammatory environment, which may result in intermittent or persistent elevations in supplemental oxygen exposure and the ongoing need for mechanical ventilation, setting up a cycle of ongoing ventilator support and further lung injury.

Nonpharmacologic Support: Nutrition, Ventilation, Noninvasive Respiratory Support, and Oxygen Saturation Targets

General nutritional recommendations for extremely preterm infants include early protein administration (through the parenteral route) and early initiation of enteral feeds (reviewed by Poindexter and

Martin, 2015). Consistent with those findings, Ehrenkranz et al. (2011) have shown that even modest decreases in energy intake in the first 3 weeks after birth increase the odds of developing BPD after adjusting for multiple other risk factors and degree of respiratory illness. Furthermore, infants with BPD have increased energy expenditure, and growth failure at 36 weeks is prevalent, progresses from 36 to 48 weeks' PMA for infants with severe BPD, and persists to 18 to 22 months corrected age for many infants with BPD (de Meer et al., 1997; Ehrenkranz et al., 2005; Natarajan et al., 2012, 2014). Thus an early aggressive approach to nutritional support, particularly for the sickest infants, mitigates the risk of BPD and its repercussions and should be balanced against the potential benefits of fluid restriction (Ehrenkranz et al., 2006; Natarajan et al., 2012, 2014).

The general approach to ventilation of the infant with evolving BPD should be one of preventing atelectasis, sustaining FRC with end-expiratory pressure, using a minimal tidal volume (usually 4–6 mL/kg) with patient-triggered ventilation, and extubating infants to noninvasive CPAP (nasal CPAP or intermittent positive pressure ventilation), optimally with variable-flow or bubble systems (Carlo et al., 2002; Ho et al., 2002; Gupta et al., 2009). The application of lower oxygen saturation targets (88%–92% vs 91%–95%) from birth did not cause harmful effects on neurodevelopment or growth at 18 to 22 months corrected age and may provide some benefit for later respiratory outcomes (Vaucher et al., 2012; Schmidt et al., 2013; Darlow et al., 2014; Stevens et al., 2014; Navarrete et al., 2016). However, lower targets from birth are not recommended because of the increased mortality seen in some randomized studies. Yet lower oxygen saturation targets later in the neonatal course (~32–35 weeks' PMA and beyond) are not associated with an increase in adverse outcomes and may decrease respiratory exacerbations (STOP-ROP Multicenter Group, 2000; Askie et al., 2003). Unresolved questions relate to the impact of higher oxygen saturation targets to minimize episodes of hypoxemia among infants with pulmonary vascular hypertensive changes and effects of higher targets on somatic growth. Many practitioners do not feel comfortable discharging infants with BPD without supplemental oxygen unless oxygen saturation is consistently greater than 92% (Abman et al., 1985; Groothuis and Rosenberg, 1987; Baraldi et al., 1997).

Pharmacologic Strategies

Caffeine

Early caffeine therapy to facilitate ventilator weaning, or to prevent or treat apnea of prematurity in extremely preterm infants, is supported by early and late follow-up from the CAP Trial and has been widely adopted (Gerull et al., 2013; Hsieh et al., 2014; Jensen et al., 2015). Caffeine is administered as a loading dose of 20 mg/kg, followed by a maintenance dose of 5 mg/kg per day, with the dose advanced up to 10 mg/kg per day as needed for ongoing apnea (Schmidt et al., 2006). It is not known if there is benefit to the initiation of caffeine in the most critically ill infants in the first days after birth, as few infants with these characteristics were enrolled in the CAP Trial (Schmidt et al., 2014). In addition, the timing of discontinuation of caffeine is unclear, as infants who are born more preterm have prolonged resolution of periodic breathing and hypoxic episodes, attenuated by prolonged caffeine therapy (Eichenwald et al., 1997; Hunt et al., 2011; Rhein et al., 2014; Coste et al., 2015). Thus the prolonged use of caffeine in these infants who are at highest risk for BPD could decrease the ongoing use of supplemental oxygen. Finally, there are no published data

regarding the effect of caffeine therapy on respiratory outcomes after neonatal discharge.

Inhaled Nitric Oxide

Multiple trials have evaluated the effect of iNO to prevent BPD. Although the metaanalysis of this preventive iNO use did not show significant benefit, only two published studies initiated iNO at a dose greater than 5 ppm, which appears to be more effective than initiation of iNO at 5 ppm (Askie et al., 2011). For instance, infants treated with iNO in the NO CLD Trial had iNO initiated at 20 ppm and received a minimum of 24 days of therapy, with iNO continued when infants were extubated, while on nasal CPAP or nasal cannula support (Ballard et al., 2006; Ballard 2007). Furthermore, the benefit of iNO in this study persisted with the assessment of respiratory outcomes at 1 year corrected age (Hibbs et al., 2008). Practitioners at many institutions have been reluctant to use iNO in preterm infants due to cost, yet iNO use is not uncommon in the highest-risk infants, although it may not provide the same benefits when used in the clinical setting (Truog et al., 2014; Ellsworth et al., 2015). The most recent data, evaluating only those studies with iNO initiated at greater than 5 ppm, suggest that there may be greater benefit of iNO on the outcome of BPD in infants of black mothers, compared with infants of nonblack mothers (Ballard et al., 2016).

Diuretics

In infants with well-developed BPD, pulmonary edema is a major component of the illness. There is clear evidence that either daily or alternate-day therapy with the loop diuretic furosemide improves lung mechanics and gas exchange in infants with established BPD (Rush et al., 1990; Hazinski, 2000). These effects may be due to diuresis or to other effects of furosemide, including pulmonary venodilation, resulting in intravascular movement of alveolar water, or to relaxation of airway smooth muscle (Cotton et al., 2012). Thiazide-type diuretics alone or in combination with spironolactone also have improved lung function in some studies.

There is no evidence for long-term benefits of diuretic therapy; nevertheless, most centers use diuretics at some point in the management of infants with BPD, particularly in infants with more severe BPD, and diuretic use in the 1 to 2 years following discharge is common (Hibbs et al., 2008; Cotton et al., 2012; Stevens et al., 2014; Guaman et al., 2015). Some metabolic effects of diuretic use are attenuated by every other day dosing, and spironolactone can counterbalance some of the electrolyte disturbances. Although an infant with chronic BPD who is chronically hypercarbic will develop a compensated respiratory acidosis, if diuretic effects on electrolyte excretion are not managed, a primary metabolic alkalosis may also develop. Additional potential complications of long-term therapy with loop diuretics include hypercalciuria with nephrocalcinosis and its sequelae and osteopenia, which can occur in these former premature infants because of decreased intrauterine mineral accretion, insufficient postnatal mineral supplementation, and the metabolic effects of the drugs. Ototoxicity is also of concern in this vulnerable population, although permanent hearing loss may be an association with more severe neonatal illness.

Bronchodilator Therapy

With established BPD, there is a significant increase in airway obstruction and persistent or intermittent wheezing in substantial proportions of infants and children with BPD (Robin et al., 2004; Fakhoury et al., 2010; Been et al., 2014; Kotecha et al., 2015).

Several studies of either short-term, inhaled, or parenteral β_2 -adrenergic agonist therapy have demonstrated improvement in infant lung function. Inhaled albuterol has been the most widely used agent, and a subset of children with BPD exhibit airway reactivity across childhood and adolescence (Robin et al., 2004; Fakhoury et al., 2010; Kotecha et al., 2015). Hazinski (2000) pointed out that there are two potential adverse effects associated with the use of β_2 -agonist drugs: (1) there can be β -agonist-induced vasodilatation, which may lead to hypoxia, and (2) β -agonist-induced augmentation of airway instability in an infant with BPD and concurrent tracheomalacia may occur. These effects may lead to clinical worsening. Hilgendorff et al. (2008) evaluated former premature infants at term-corrected age and found bronchodilator-responsive airway disease in 18/27 infants despite no clinical evidence of airway obstruction. However, an additional four infants had a “paradoxical” response to the medication, consistent with airway malacia.

As substantial proportions of infants and children with BPD exhibit airway reactivity, a trial of bronchodilator therapy may be indicated in symptomatic children and is probably a common practice, as bronchodilator exposure is frequent in both inpatient and outpatient settings (Hibbs et al., 2008; Gauman et al., 2015; Slaughter et al., 2015). Although the β_2 -agonist therapy with albuterol is the drug that has been most frequently studied, there is rationale for addition or substitution of ipratropium (an anticholinergic) for those infants without positive response to albuterol (Iyengar and Davis, 2015). Evaluation of routine bronchodilator therapy in infants with established BPD should be studied to identify if this use of bronchodilators could attenuate later respiratory morbidity.

Postnatal Corticosteroids

As discussed earlier, there is no study that convincingly supports the use of either systemic or inhaled corticosteroids for prevention or treatment of developing BPD. However, the use of inhaled and systemic steroids with established BPD remains prevalent (Hibbs et al., 2008; Stevens et al., 2014; Gauman et al., 2015). Current data are limited as to the risk versus benefit for both short-term and long-term outcomes in these infants. It may be most appropriate to trial these interventions in the setting of intercurrent infection, because increased inflammation is likely prominent in respiratory exacerbations, similar to other populations of patients with lung disease.

Pulmonary Hypertension

Although it is known that infants dying with BPD have dysmorphic pulmonary vascular development (Abman, 2008), the definitions of pulmonary hypertension used in the preterm population are variable, and the true prevalence of pulmonary hypertension in the setting of BPD is unknown. Some practitioners recommend periodic screening echocardiograms (Mourani and Abman, 2015; Nagiub et al., 2015), but the sensitivity and specificity of this technique are not adequate, in general, including infants with lung disease in an experienced center (Mourani et al., 2008). In any population, the gold standard for diagnosis of pulmonary hypertension is by cardiac catheterization. However, pulmonary hypertension as defined by echocardiogram does not universally portend a poor prognosis, with 89% of former premature newborns demonstrating improvement over time (Khemani et al., 2007). In prospective studies of at-risk infants, a relatively low proportion have elevated right heart pressures by echocardiogram near term, and these abnormalities are more common in infants with BPD than in

those without BPD (Mirza et al., 2014; Mourani et al., 2015). Although therapies for chronic treatment of pulmonary hypertension have shown efficacy in older patient populations, the risk–benefit profile for infants and young children is unknown, and empiric therapy by echocardiogram alone is not recommended (Abman et al., 2015).

Future Directions

Given the pathobiology of BPD, there are multiple potential targets for prevention of the disease, although, ultimately, the multifactorial nature of the disorder may require a multipronged strategy. Caffeine alone, in the CAP Trial, for instance, still left over one-third of infants with a diagnosis of BPD, with the sickest infants not enrolled. The timing of intervention is also likely to be important, as suggested in trials of caffeine and iNO. Selection of extremely high-risk newborns in the first week after birth may be the best strategy, and intervention beyond the second week of life may not be effective, as BPD may already be established. Treatments such as budesonide suspended in surfactant, intratracheal administration of mesenchymal stem cells, and antioxidant therapies currently hold the most promise for benefit among the highest-risk infants, given the potential to counteract inflammation and other effects of supplemental oxygen exposure, but definitive clinical trials evaluating these therapies will be challenging. Furthermore, these therapies are targeted at infants who remain intubated, while additional infants with noninvasive ventilation remain at risk of BPD and its repercussions.

Summary

BPD remains the most common form of chronic lung disease in children, with up to 10,000 new cases in the United States each year. Morbidity and comorbidity associated with the disorder are high, with chronic illness and long-term neurodevelopmental effects, accompanied by financial costs to families and society. Late pulmonary effects of the new BPD are also not yet well defined, although respiratory function impairments are present in surviving adults (reviewed by Islam et al., 2015). Broadly applied early ventilatory and nutritional approaches appear critical to overall prevention of BPD. However, for extremely preterm infants who

Outcome

Infants with severe BPD have ongoing risk of mortality; approximately 10% of infants died after the diagnosis of BPD in a study from quaternary referral centers (Murthy et al., 2014). Mortality is higher among infants with a diagnosis of pulmonary hypertension, 38% in one report, with those with severe pulmonary hypertension (systemic-to-suprasystemic) more likely to die (Khemani et al., 2007). BPD is also associated with poor neurodevelopmental outcomes in long-term follow-up assessments (Ehrenkranz et al., 2005; Wilson-Costello et al., 2009). Poor nutrition, impaired growth, and prolonged and recurrent hospitalization probably contribute to these poor outcomes (Wood et al., 2003; Watson et al., 2009). Additional morbidities associated with BPD include airway malacia, which is common among infants who ultimately undergo tracheostomy, and systemic hypertension (Sahu et al., 2013; Wai et al., 2017). Children with BPD have increased rates of pulmonary hospitalization and medication use in the first 1 to 2 years of life, a pattern that persists to at least 6 years of age (Hennessy et al., 2008). In addition, cost of care in the first year of life was 30% greater for infants with BPD than at-risk infants without BPD in one study (Watson et al., 2009). Given the multiple systems involved, it is likely that these infants would benefit from multidisciplinary follow-up care. Rhein et al. (2012) demonstrated that infants with subspecialty follow-up had similar rates of hospitalization and emergency department visits, after adjusting for risk factors, although we might expect these higher-risk infants to have greater utilization of healthcare resources.

are at greatest risk due to genetic predisposition, fetal environment, or more severe cardiorespiratory illness, there are limited early interventions that have been successfully implemented in practice to prevent BPD and its repercussions. For infants with established BPD, there is great variability in therapeutic approach, which may partially reflect the heterogeneity of the condition but also reflects a lack of data for therapies that can best decrease the respiratory morbidity associated with BPD and preserve lung growth and function later into childhood and beyond.

Surgical Disorders of the Chest and Airways

BENJAMIN A. KELLER, SHINJIRO HIROSE, AND DIANA L. FARMER

KEY POINTS

- Prompt diagnosis and early intervention are key in salvaging infants with life-threatening surgical disorders of the airway and chest.
- Improved prenatal ultrasound has shifted the diagnosis of disorders of the chest and airways into the fetal period.
- Increased utilization of video-assisted thoracoscopic surgery for congenital thoracic lesions has made surgical intervention on the infant chest less invasive and more tolerable.

Anomalies of the Airways

Nasopharyngeal Obstructive Disorders

Respiratory distress caused by nasal obstruction may manifest as a serious, life-threatening event shortly after birth. Because newborns are preferential nasal breathers for the first 2 to 3 weeks after birth, nasal obstruction may cause severe cyanosis, particularly during oral feedings, with airway obstruction relieved only when the mouth is open to cry (Ramsden et al., 2009). There are several causes of neonatal nasal obstruction, including congenital choanal atresia, nasal pyriform aperture stenosis, nasolacrimal duct cyst, and nasal hypoplasia. Buckling or, less commonly, dislocation of the nasal septum because of birth trauma can also cause breathing problems; most cases respond to decongestant and steroid nasal drops, but dislocations require surgical manipulation (Prescott, 1995).

Congenital Choanal Atresia

Caused by persistence of the buccopharyngeal membrane, congenital choanal atresia occurs in between 1 in 5000 and 1 in 9000 births and has a significant female preponderance. In the majority of choanal atresia cases, the obstructing membrane is of mixed bony and membranous composition (Brown et al., 1996). Choanal atresia is more frequently unilateral (~2/3 of cases) and right sided; bilateral malformations are more serious and constitute an emergency at birth (Szeremeta et al., 2007; Ramsden et al., 2009). Over half of all cases are associated with other congenital anomalies, bilateral cases more so than unilateral (Hall, 1979; Burrow et al., 2009). The most common collection of anomalies was originally termed the *CHARGE association*, consisting of some combination of colobomas of the eyes, heart defects, atresia of the choanae, retardation

of growth or development, genitourinary defects, and ear anomalies associated with deafness (Pagon et al., 1981). The association was officially named *CHARGE syndrome* in 2004, when a common mutation in the *CHD7* gene on chromosome 8 was identified in 60% of cases (Visser et al., 2004).

Because the newborn is a preferential nasal breather, there may be serious difficulties soon after birth, especially in cases of bilateral atresia. Unilateral atresia may present simply with unilateral discharge and feeding difficulties but may not present until later in childhood. The inability to pass a 5- or 6-French catheter through the nose may suggest the diagnosis. Computed tomography (CT) of the nasopharynx with intranasal contrast is the method of choice for making a definitive diagnosis and for evaluating the nature and severity of nasal obstruction (Benjamin, 1985; Crockett et al., 1987).

Emergent management of choanal atresia is focused on ensuring that the oropharyngeal airway is patent, which may necessitate endotracheal intubation. A McGovern nipple, an orogastric tube, or a modified endotracheal tube can be used to overcome the seal between the palate and the tongue (Fulton et al., 2007). Tracheostomy is rarely necessary and typically only required when associated with other anomalies (Asher et al., 1990).

Surgical repair is the mainstay of treatment and can be performed within a few days of birth. Patency can be established by various methods according to surgeon preference. Correction can be accomplished using the transnasal approach under endoscopic visualization and relieving the obstruction using dilators (Stahl and Jurkiewicz, 1985). The transnasal approach works best with thin buccopharyngeal membranes but tends to have higher recurrence and reoperation rates (Samadi et al., 2003; Hengerer et al., 2008). While temporary stenting has been used to decrease restenosis rates, the use of stents remains controversial. It may not prevent restenosis and can be associated with complications, including alar injury, columellar tear, and vestibular stenosis (Strychowsky et al., 2016). The transpalatal approach entails surgical correction of the offending defect and is typically performed for thick bony membranes. However, despite the minimal rate of reoperation, this approach is associated with a higher rate of palate growth deformities. In an attempt to avoid altering palate growth, modern endoscopic biting and drilling instruments were introduced to improve the transnasal technique (Stankiewicz, 1990; Josephson et al., 1998), and studies continue to demonstrate increasing support for the endoscopic repair of choanal atresia (Ramsden et al., 2009).

Congenital Nasal Pyriform Aperture Stenosis

Nasal pyriform aperture stenosis is a rare cause of nasal obstruction and should be suspected when encountering difficulty in passing a nasal catheter. Infants usually present with noisy breathing and respiratory distress that worsens with feeding and improves with crying (Ramadan et al., 1995). Pyriform aperture stenosis is characterized by excessive bone formation in the medial nasal processes of the maxillary bone. The condition may be isolated or associated with other anomalies, such as a solitary maxillary central incisor tooth or, more seriously, midline defects such as pituitary hypoplasia with endocrine insufficiency, diabetes insipidus, or other manifestations of holoprosencephaly and craniosynostosis (Beregszaszi et al., 1996; Godil et al., 2000; Van Den Abbeele et al., 2001). Similar to choanal atresia, an oral airway may be necessary to relieve the breathing difficulty. Although the obstruction can be suitably demonstrated by CT of the nasopharynx, because of its high association with holoprosencephaly, a karyotype analysis and brain CT and/or magnetic resonance imaging (MRI) may be required if brain abnormalities are suspected (Truong and Oudjhane, 1994; Devambez et al., 2009). In most cases, nasal obstruction is mild and may respond to nasal decongestants. In refractory cases of obstruction, usually when the pyriform aperture is less than 5.7 mm, sublabial surgery is necessary to remove excessive bone, and nasal stenting is required (Tate and Sykes, 2009; Wormald et al., 2015). Novel methods of rapid maxillary expansion to enlarge the pyriform aperture using custom palate expansion devices are being investigated with early success (Collares et al., 2015).

Pierre Robin Syndrome (Robin Sequence)

Although this pattern of upper airway problems was first described by Pierre Robin in 1923, characterization of Pierre Robin syndrome remains difficult and controversial. A constellation of anomalies within the spectrum of cleft palate, micrognathia, and glossoptosis, the Pierre Robin syndrome has relatively recently been linked to mutations in the *SOX9* gene (Jakobsen et al., 2007; Benko et al., 2009). Given the varying definitions published, the incidence of Pierre Robin syndrome is difficult to pinpoint; it has been reported to occur in anywhere from 1 in 8500 to 1 in 20,000 births (Breugem and Mink van der Molen, 2009). It is the hypoplastic development of the mandible that is of clinical significance, as the micrognathia can lead to airway obstruction and cyanosis (Cozzi and Pierro, 1985). Obstruction is common when the infant is in the supine position, during feeding, and in active sleep, when pharyngeal muscle tone is absent. Excessive air swallowing, followed by gastric distention, vomiting, and tracheal aspiration, is a frequent problem. The pharyngeal obstruction is maintained by the generation of large negative pressures in the lower pharynx during inspiration and swallowing (Fletcher et al., 1969). Chronic obstruction leads to carbon dioxide retention, failure to thrive, and development of pulmonary hypertension with right-ventricular failure (Johnson and Todd, 1980).

As with the imprecise diagnosis of Pierre Robin syndrome, the severity of respiratory obstruction and the management indicated are varied. Mild cases may present with only mild glossoptosis, and because oral feeds are tolerated without respiratory obstruction, these cases can be managed by side-to-side nursing (Cole et al., 2008; Evans et al., 2011). In the event of respiratory symptoms with feedings or failure to thrive, a nasogastric tube for feedings may be required (Cole et al., 2008). In severe cases of respiratory distress, nasopharyngeal intubation should be performed, typically by passing a 3.5-mm tube through the nose and into the hypopharynx (Stern et al., 1972; Heaf et al., 1982). This prevents the

generation of negative pressure and greatly relieves the respiratory difficulty. The nasopharyngeal tube may be left in place for weeks or even months with adequate lavage and suctioning. Other treatments include tongue–lip adhesion surgery (glossopexy) to hold the tongue forward and tracheostomy if a nasopharyngeal tube does not adequately relieve the obstruction (Gilhooly et al., 1993; Cozzi et al., 2008). Mandibular distraction and velar extension appliances have been introduced as attempts to avoid tracheostomy (Denny and Kalantarian, 2002; Buchenau et al., 2007). Nutrition can be maintained with a hypercaloric formula fed by nasogastric or gastrostomy tube. With adequate airway management and the passage of time, the problem becomes less threatening, especially after a few months, when the infant gains better control of the tongue (Mallory and Paradise, 1979). Oral feedings can then be introduced, usually with a long lamb's nipple to help hold the tongue forward. With adequate nutrition and growth of the mandible, the problem usually resolves by 3 to 12 months of age, when cleft palate repair can safely take place.

Glossoptosis–Apnea Syndrome

Pierre Robin syndrome is not the only condition characterized by mechanical obstruction by the tongue. Infants with Beckwith–Wiedemann syndrome may have considerable breathing difficulties and apnea due to the associated macroglossia (Kamata et al., 2005). Infants with a normal-sized tongue who also have conditions such as unilateral choanal atresia, choanal stenosis, or swelling of the nasal mucosa may generate considerable negative pressure in the pharynx; this, combined with inadequate muscular control over the tongue, may lead to pharyngeal obstruction with respiratory distress, cyanosis, and severe episodes of apnea (Cozzi and Pierro, 1985).

Pharyngeal Incoordination

While the tongue provides the majority of force to move a food bolus into the esophagus, weakness and incoordination of the pharyngeal musculature can lead to disordered swallowing (Massey and Shaker, 2006). This incoordination causes choking and cyanosis with feedings and may be complicated by aspiration pneumonia (Avery and Fletcher, 1974). Affected infants have difficulties in swallowing their own secretions. The condition may be seen in infants with severe hypoxic–ischemic encephalopathy and pseudobulbar palsy, Arnold–Chiari malformation, Möbius syndrome, and other facial malformations. Electromyography of the facial and pharyngeal muscles during rest, crying, and eating can aid in diagnosis (Baudon et al., 2009). Specifically, it can be used to assess the sucking and swallowing coordination in infants during bottle feeding. Drugs with antimuscarinic effects, such as atropine, can decrease secretions and may produce some relief. Although some infants may gradually improve, long-term management may require initiation of tube feedings or even gastrostomy in children who fail to improve.

Laryngeal Deformities

Laryngomalacia (Congenital Laryngeal Stridor)

A relatively common condition, congenital laryngeal stridor or laryngomalacia is the most frequent cause of stridor in infants (Zoumalan et al., 2007). Laryngomalacia is characterized by the prolapse of poorly supported supraglottic structures—the arytenoids, the aryepiglottic folds, and the epiglottis—into the airway during inspiration, causing respiratory obstruction and difficulty with feeding (Olney et al., 1999). Despite loud, high-pitched inspiratory

stridor and significant chest retractions that typically present during the first month of life, the infant seldom has cyanosis, hypercarbia, notable feeding difficulty, failure to thrive, or an abnormal cry (Richardson and Cotton, 1984). Laryngomalacia is worse in the supine position, with the neck flexed, and subsides in the prone position, with the neck extended (Cotton and Richardson, 1981). Obstruction is worse during episodes of agitation and lessens when the infant is calmed. Severe forms of laryngomalacia may cause apneic events, pulmonary hypertension, or difficulties with feeding and/or weight gain. Although a CT scan is effective at demonstrating the abnormal prolapse of the aryepiglottic folds supporting the diagnosis (Galvin et al., 1994), confirmation should be obtained at laryngoscopy (Friedman et al., 1990; Wiatrak, 2000), with specific care to avoid fixating the supraglottic tissues with the instrument. Some practitioners prefer to pass a flexible fiberoptic bronchoscope through the nose (Berkowitz, 1998), which does not disturb the supraglottic tissues. In some cases, gastroesophageal reflux or episodes of obstructive apnea may be associated with this condition (Belmont and Grundfast, 1984). Synchronous airway abnormalities are found in up to 30% of infants, including vocal cord paralysis, tracheomalacia, and subglottic stenosis (Simons et al., 2016). Thus the evaluation of stridor must include the examination of the entire upper airway and upper digestive tract (Friedman et al., 1984). Stridor associated with laryngomalacia is usually loudest at 4 to 8 months, and most cases resolve with conservative management around 12 to 24 months (Thompson, 2007). Conservative therapy entails positioning the infant prone as much as possible, and most demonstrate improvement over roughly 18 months (Smith and Catlin, 1984). Approximately 20%, however, will have severe obstructive apnea, cor pulmonale, and/or failure to thrive and require a surgical intervention. In these cases supraglottoplasty may be indicated, with 71% having complete resolution of symptoms and 94% having symptom improvement postoperatively (Garritano and Carr, 2014). Tracheostomy is reserved for supraglottoplasty failures (Richter and Thompson, 2008).

Vocal Cord Paralysis

Unilateral cord paralysis is usually left sided and typically presents without marked stridor or retractions manifesting as aspiration (Parikh, 2004). The infant may cough and choke during feedings, as laryngeal closure with swallowing is impaired. The condition is most frequently secondary to iatrogenic injury, usually caused by excessive stretching of the neck during delivery or injury during surgery; however, it can also be due to neurologic disorders (de Gaudemar et al., 1996). Right-sided vocal cord paralysis has been reported as a complication of extracorporeal membrane oxygenation (ECMO) (Schumacher et al., 1989), presumably as a result of the surgical dissection for insertion of the catheters. Ligation of a patent ductus arteriosus (PDA) has also been associated with a high rate of left-sided vocal cord paralysis, probably secondary to recurrent laryngeal nerve injury during dissection. Recent studies have found that 40%–54% of low birth weight children who undergo PDA ligation have a left vocal cord paralysis (Benjamin et al., 2010; Røksund et al., 2010). This increases their risk of developing bronchopulmonary dysplasia (BPD), reactive airway disease, and feeding problems requiring a gastrostomy tube. Lying the infant on the paralyzed side may decrease the amount of stridor, as the affected cord falls away from the midline (Cotton and Richardson, 1981). Diagnosis can be confirmed with flexible nasolaryngoscopy but may require direct laryngoscopy in the operating room (Fig. 49.1). The condition tends to improve over a period of several weeks or months, and speech and swallow therapy can be used in cases where improvement is not seen. Generally, medialization of the vocal cord is not recommended in neonates less than 6 months of age; however, in children with gross aspiration and severe phonotory difficulty, it may be required. Tracheostomy is preferred in severe cases of respiratory obstruction (Parikh, 2004).

Bilateral cord paralysis is a much more serious condition, accompanied by high-pitched inspiratory stridor; frequently, however, the cry is normal. Usually, severe central nervous system problems are to blame, such as hypoxic–ischemic encephalopathy, cerebral hemorrhage, Arnold–Chiari malformation, hydrocephalus,

• **Fig. 49.1** Vocal Cord Paralysis. (A) Bronchoscopy of a neonate demonstrating a normal glottis. (B) Bronchoscopy of an infant with bilateral true vocal cord paralysis causing obstruction. (Courtesy of Dr. Jamie Funamura, Assistant Professor, University of California, Davis Health System, Department of Otolaryngology, Sacramento, CA.)

or brainstem dysgenesis. Associated problems may include pharyngeal incoordination with swallowing difficulty and esophageal dysfunction, recurrent apnea episodes, and tracheal aspiration of mucous secretions and formula. The stridor may resolve slowly if brain swelling subsides after birth, as is the case with ventriculoperitoneal shunt placement. The diagnosis may be suspected at laryngoscopy but should be confirmed by flexible fiberoptic bronchoscopy, rigid bronchoscopy, or ultrafast cine CT scan. Tracheostomy is frequently required in about 50%–60% of patients (Daya et al., 2000; Lesnik et al., 2015), and the prognosis usually is poor secondary to the underlying problems.

Laryngeal Atresia

Laryngeal atresia is the result of failed recanalization of the larynx during embryologic development, resulting in a newborn with complete laryngeal obstruction presenting with severe respiratory distress. In some cases the larynx may be completely obstructed by a laryngeal web, seen in the delivery room during attempts to intubate the cyanotic infant. An endotracheal tube sometimes can be forced beyond the obstruction into the trachea. Otherwise, a large-bore needle should be inserted percutaneously into the trachea to maintain marginal gas exchange while preparations for emergency tracheostomy are made. Most infants with laryngeal atresia have other lethal malformations (Smith and Catlin, 1984). Most cases are now diagnosed prenatally from ultrasound findings consistent with congenital high airway obstruction syndrome (CHAOS), such as polyhydramnios and enlarged hyperechoic lungs with an associated flattened or inverted diaphragm (Hedrick et al., 1994; Kalache et al., 1997). The mother may be evaluated for ascites or hydrops fetalis due to impaired venous return to the heart, and the amniotic fluid lecithin level may be very low in such cases. In the absence of other lethal malformations, the characteristic ultrasound diagnosis may permit preparations for emergency tracheostomy after delivery of the infant or an ex utero intrapartum treatment (EXIT)-to-airway procedure, discussed later. Survivors of fetal intervention for CHAOS have now been seen (Hirose et al., 2004; Elliott et al., 2013).

Congenital Subglottic Stenosis

Congenital subglottic stenosis, manifesting as inspiratory stridor from birth, is caused by partial obstruction of the cricoid probably due to incomplete canalization of the cricoid ring. In a full-term infant the normal subglottic lumen is 4.5–5.5 mm in diameter, whereas that of a preterm neonate is 3.5 mm in diameter. A subglottic diameter of 4 mm or less in a full-term infant or 3 mm or less in a premature infant is consistent with a diagnosis of subglottic stenosis. Subglottic stenosis is diagnosed by direct laryngoscopy supplemented with rigid bronchoscopy and chest radiography to evaluate other airway lesions and/or concomitant lung disease, as the latter may be common in the premature infant. Treatment consists of balloon dilation or endoscopic lysis with a carbon dioxide laser in cases of membranous stenosis. However, most cases severe enough to require intervention are cartilaginous and require an anterior cricoid split, obviating the need for and complications of tracheostomy in most cases (Cotton and Seid, 1980; Smith and Catlin, 1984; Schroeder and Holinger, 2008).

Congenital Subglottic Hemangioma

Subglottic hemangiomas are rare, accounting for 1.5% of all congenital abnormalities of the larynx (Pransky and Canto, 2004).

They often occur in association with a cutaneous hemangioma and may cause inspiratory stridor and expiratory wheezing that progress with enlargement of the tumor (Cotton and Richardson, 1981; Orlow et al., 1997). This diagnosis is suspected when asymmetric subglottic narrowing is seen on plain radiographs and is confirmed by flexible and rigid endoscopy demonstrating a sessile vascular lesion, most commonly in the posterolateral subglottis (Rahbar et al., 2004; Ahmad and Soliman, 2007). Although some practitioners have advocated high-dose corticosteroid therapy (Brown et al., 1972) and others have tried intralesional injections of steroids, in many cases intubation or tracheostomy is eventually required. Results of removal by carbon dioxide or potassium titanyl phosphate (KTP) laser have been encouraging, enabling treatment without tracheostomy; however, associated complications such as subglottic stenosis have been reported (Healy et al., 1984; Kacker et al., 2001; Ahmad and Soliman, 2007). Finally, case reports using beta blockers (propranolol and acebutolol) have been successful in causing regression of subglottic hemangiomas, preventing the need for tracheostomy altogether (Blanchet et al., 2010).

Laryngotracheoesophageal Cleft (Congenital Laryngeal Cleft)

In laryngotracheoesophageal cleft, a longitudinal communication is present between the airway and the esophagus, stretching from the larynx into the upper trachea or sometimes as far as the carina. This rare condition is reported in 1 in 10,000 to 1 in 20,000 births and is caused by failed fusion of the two lateral growth centers of the posterior cricoid cartilage, preventing proper fusion of the posterior cricoid lamina (Pezzettigotta et al., 2008). Affected infants have respiratory distress with inspiratory stridor and cyanosis, associated with tracheal aspiration of saliva and feedings. Chest radiographs may show evidence of aspiration pneumonia, and the cine esophagogram shows contrast material spilling into the trachea. The diagnosis can be established with direct laryngoscopy and bronchoscopy. Given the high association with other congenital anomalies and syndromes, such as tracheal atresia, tracheoesophageal fistula, and Opitz–Frias syndrome, a thorough evaluation of all organ systems and genetic karyotype are recommended.

Laryngotracheoesophageal clefts are classified, by severity of symptoms, into four groups (types I–IV), which are used to determine the management strategy and the need for surgical intervention. For all types, initial management involves adequately securing the airway with an endotracheal tube or tracheostomy (Richardson and Cotton, 1984). Mild cases can sometimes be managed by conservative therapy, including swallow rehabilitation and antireflux medication (Pezzettigotta et al., 2008). In those who fail conservative management, endoscopic therapy including injection augmentation of the cleft may be attempted (Mangat and El-Hakim, 2012). More severe cases require extensive reconstruction employing an anterior translaryngotracheal approach or even a partial upper sternotomy. Despite these reconstruction attempts, mortality remains high, at nearly 50% among all types of clefts and higher in cases with associated congenital anomalies and type IV clefts (Roth et al., 1983; Myer et al., 1990; Simpson et al., 1996).

Tracheal Deformities and Other Tracheal Disorders

Tracheal Agenesis

Tracheal agenesis is a rare condition that occurs in less than 1 in 50,000 births (Demircan et al., 2008). The trachea can be atretic

just below the vocal cords but is most often absent all the way down to the carina (Altman et al., 1972). Clinical manifestations include severe distress, absence of vocal sound, and severe cyanosis. Affected infants usually have additional congenital anomalies within the VACTERL association, including tracheoesophageal fistulas, severe cardiac malformations, and sometimes renal and anal anomalies (Mohammed et al., 2016). Prenatal diagnosis is difficult, but prenatal presentation may manifest as CHAOS. If diagnosed prenatally, delivery via EXIT should be arranged to maximize the chances for survival (Vaikunth et al., 2009). Postnatal diagnosis should be suspected in cases of respiratory distress with immediate hypoxia, no audible cry, and a mechanical inability to intubate (Demircan et al., 2008). Despite the presence of a larynx, intubation cannot be accomplished at delivery; however, if the tracheal tube is positioned in the esophagus and connected to a mechanical ventilator, reasonable gas exchange can be obtained via the tracheoesophageal fistula (Sandu and Monnier, 2007). When the tracheal atresia is high, a tracheostomy can be performed in the remnant tracheal tissue. If survival seems possible, gastric division and a gastrostomy for feeding should be performed. Reconstructive surgery is not likely to be successful, however, and the prognosis is extremely poor, if not because of poor ventilation, then because of the underlying malformations.

Congenital Tracheal Stenosis

In congenital tracheal stenosis, a segment of the trachea is narrowed, usually starting in the subglottic region. The affected segment may be short or long; occasionally, the entire trachea is hypoplastic, and the bronchi may be involved. This disorder affects 1 in 64,500 live births and is usually caused by complete or nearly complete cartilage rings that narrow the trachea (Hewitt et al., 2016). Affected patients may have inspiratory stridor, expiratory wheezing, feeding difficulties, and experience cyanotic episodes. Mild inflammation and small mucous plugs may cause life-threatening deterioration. In up to 60% of cases, other congenital malformations are also present, such as vascular ring anomalies, congenital heart defects, tracheoesophageal fistula (especially the H type), and hemivertebrae (Benjamin et al., 1981). There also is an association with pulmonary agenesis (Volland et al., 1986). A series of cases without accompanying defects have been reported in premature infants who presented with difficulties at tracheal intubation (Hauff et al., 1988).

Patients with this deformity usually can be intubated, but the endotracheal tube cannot be advanced and should not be forced. Mechanical ventilation with generous levels of positive end-expiratory pressure (PEEP) may help stabilize the infant. Tracheostomy is not indicated and interferes with making the diagnosis (Nakayama et al., 1982). Sometimes the diagnosis can be made by inspiration and expiration chest radiographs, using air as the contrast medium. However flexible fiberoptic bronchoscopy in the neonatal intensive care unit (NICU) or rigid bronchoscopy in the operating room is usually required for diagnosis (Lobe et al., 1987). Because it is important to examine the lower limits of the stenosis, it may be necessary to proceed with tracheobronchography, but this may sometimes cause acute decompensation and is controversial (Loeff et al., 1988; Hewitt et al., 2016). Today, ultrafast cine CT scan and MRI have become useful diagnostic techniques to define the lower limits of the stenosis (Galvin et al., 1994; Rimell et al., 1997). In addition, three-dimensional (3D) CT reformats provide valuable information on the trachea–cardiovascular relationship and can allow for 3D printing of models to rehearse complex surgical interventions (Hewitt et al., 2016).

In most cases, the stenosis requires treatment of some kind in the operating room. Balloon dilation alone is not likely to be successful in the case of a complete tracheal cartilage ring, because cartilage cannot be stretched. For short-segment stenosis, balloon dilation with laser may be used: at rigid bronchoscopy, the cartilage ring is split at the midline posterior aspect using the KTP laser, and the bronchoscope is advanced with the aid of serial balloon dilations (Othersen et al., 2000). Some groups have used metallic stents to prevent restenosis with long-term success; however, granulation tissue over the stent can make removal difficult (Maeda et al., 2013). For longer-segment stenosis, Longaker et al. (1990) described segmental resection of the stenosis with end-to-end anastomosis to shorten the trachea, followed by serial balloon dilations through a rigid bronchoscope. Backer et al. (1998) described the successful use of free autografts of resected trachea for this type of tracheoplasty. However, for long-segment stenosis, slide tracheoplasty has become the standard treatment (Lipshutz et al., 2000). In this procedure, the stenosis is transected in the middle, the upper segment is incised longitudinally along the anterior aspect, the lower segment is incised longitudinally at the posterior aspect, the incised segments are slid over one another, and the edges are anastomosed, effectively shortening the trachea while widening the narrowed lumen.

The use of cardiopulmonary bypass has improved treatment and is advocated by some as averting the need for complex anesthesiology techniques (Loeff et al., 1988). After midline sternotomy, tracheal resection, and tracheoplasty with shortening of the trachea, the patient may need fixation in a brace for at least 6 weeks to maintain neck flexion and prevent excessive stretching of the anastomosis (Nakayama et al., 1982). Premature infants with congenital tracheal stenosis cannot undergo tracheal resection and tracheoplasty with cardiopulmonary bypass procedures. For these patients, aggressive balloon dilations are recommended, with splitting of the weaker posterior aspect of the tracheal rings (Messineo et al., 1992). With improvements in surgical techniques and the addition of ECMO to complex repairs, survival rates have improved to greater than 80% (Butler et al., 2014). Those patients who have concurrent distal bronchial stenosis or distal bronchomalacia have slightly lower survival rates (Hewitt et al., 2016).

Tracheobronchomalacia (Tracheomalacia)

Tracheobronchomalacia is characterized by dynamic collapse of the trachea during breathing secondary to delayed development of tracheal cartilage. This condition may be primary or associated with tracheoesophageal fistula, BPD, extrinsic tracheal compression, or prolonged intubation (Sotomayor et al., 1986). Tracheobronchomalacia should be suspected in infants presenting with respiratory distress, cyanotic spells, or persistent respiratory symptoms including expiratory stridor, recurrent respiratory infections, or persistent or recurrent wet cough (Masters, 2009). Chest radiographs are usually normal, with only a 62% specificity in diagnosing tracheobronchomalacia (Walner et al., 1999). With improvements in multidetector CT scanners and ultrafast cine CT scanners, diagnosis can be made in with improved accuracy (Lee and Boiselle, 2009; Goo, 2013). Bronchoscopy remains the gold standard for diagnosis, which shows approximation of the anterior and posterior walls of the trachea during expiration (Saltzberg, 1983). The bronchoscope may support the walls of the trachea, alleviating the respiratory distress by passage of the bronchoscope to the carina, while potentially disguising the extent of the abnormalities.

Factors associated with the development of tracheomalacia include immaturity, higher mean airway pressure, and prolonged

mechanical ventilation (Downing and Kilbride, 1995). Affected infants may have significant dynamic compression of the trachea. Because the trachea of premature infants is very compliant and may be excessively stretched and injured during mechanical ventilation, very immature infants are particularly prone to tracheomalacia. Some premature infants have greatly enlarged tracheas or tracheomalacia after mechanical ventilation (Bhutani et al., 1986).

Many infants with tracheomalacia spontaneously improve by 1 to 2 years of age, when the cartilage has become strong enough to support tracheal patency and airway caliber increases (Sandu and Monnier, 2007). Severe cases with life-threatening episodes of airway obstruction necessitate tracheostomy with an elongated tracheostomy tube. However, current treatments for milder cases include tracheal intubation with continuous positive airway pressure (CPAP) or PEEP, which prevents tracheal collapse, and aortopexy (fixation of the aorta to the sternum), which has the effect of supporting the attached trachea (Wiseman et al., 1985; Jacobs et al., 1994; Dave and Currie, 2006). Many of the most severely affected patients respond well to aortopexy (McCoy et al., 1992).

Tracheal Compression by Vascular Rings

Tracheal compression can be caused by several factors: (1) a double aortic arch, (2) a right aortic arch, (3) a left-sided origin of the (right) innominate artery, (4) a right-sided origin of the left common carotid artery, or (5) an anomalous origin of the left pulmonary

artery from the right pulmonary artery (Hendren and Kim, 1978). With a right aortic arch, the trachea is compressed by the main pulmonary trunk, aortic arch, and ligamentum arteriosus. The anomalous innominate or common carotid arteries form a tight crotch, which impinges on the anterior trachea. The anomalous left pulmonary artery returns to the left by passing between the esophagus and the trachea, compressing the trachea between the right and the left pulmonary arteries. Infants with tracheal compression have inspiratory stridor and expiratory wheezing, with symptoms usually appearing later in the neonatal period. Affected infants often lie with the head and neck hyperextended to stretch the trachea and make it less compressible. If the esophagus is compressed, feeding is associated with regurgitation.

There are several methods of diagnosis. The chest radiograph may show mild overinflation, a right-sided aorta, and, with appropriate technique, evidence of tracheal narrowing. A barium swallow examination may show indentation of the esophagus. Bronchoscopy should reveal a pulsatile mass with narrowing near the carina (Fig. 49.2A–B). Cross-sectional imaging with CT and MRI has proven to be accurate in defining most vascular malformations and can give detailed imaging of the surrounding anatomy (Hernanz-Schulman, 2005)(see Fig. 49.2C). While echocardiography is less reliable in making the diagnosis of a vascular ring, it was recently demonstrated that prenatal diagnosis by ultrasound avoided unnecessary delays in the repair of symptomatic vascular rings and

• **Fig. 49.2** Pulmonary Artery Sling. (A) Bronchoscopy of a normal distal trachea just above the level of the carina. (B) Bronchoscopy of a trachea with external compression by a vascular ring; in this case a pulmonary artery sling. (C) Contrast-enhanced computed tomography demonstrating the anomalous left pulmonary artery passing behind the trachea and in front of the esophagus. Compression of the trachea can be seen. (Courtesy of Dr. Jamie Funamura, Assistant Professor, University of California, Davis Health System, Department of Otolaryngology, Sacramento, CA.)

that repair on identification of symptoms prevented the development of secondary tracheobronchomalacia (Rimell, 1997; Tuo et al., 2009). Treatment involves surgical division of the vascular ring. Recently, minimally invasive techniques including a video-assisted thorascopic approach and endoscopic robotic techniques have been employed (Al-Bassam et al., 2007; Suematsu et al., 2005). After surgical division of the vascular ring, the respiratory distress may persist for weeks or longer because of localized tracheal deformity (either stenosis or tracheomalacia), emphasizing the need for immediate repair on diagnosis. In cases of isolated vascular rings, repair provides cure with minimal postoperative complications (Ruzmetov et al., 2009).

Tracheal Compression by Extrinsic Masses

The trachea may also be compressed by a bronchogenic cyst, an enteric duplication cyst, a thoracic neurogenic tumor, or a mediastinal teratoma (Benjamin, 1980). These may be demonstrated by anteroposterior and lateral chest films and are especially apparent on CT scan. Such masses may also compress the esophagus and can be demonstrated with a barium swallow.

Congenital High Airway Obstruction Syndrome and the Ex Utero Intrapartum Treatment Procedure

CHAOS actually describes a spectrum of rare anomalies, including laryngeal web, laryngeal atresia, laryngeal cyst, and tracheal atresia or stenosis. Most cases are sporadic, with the true incidence unknown, and thus the natural history of this disease is not well known. CHAOS is characterized by enlarged lungs, dilated distal airway, everted diaphragm, ascites, and ultimately nonimmune hydrops fetalis. Prenatal diagnosis is becoming more common with the progress of ultrasound and MRI techniques. The exact nature of the airway obstruction may not be entirely clear, however, and the time required to establish a safe airway soon enough after delivery carries various risks, including anoxic brain injury.

As with any anomaly that causes either direct respiratory airway obstruction or airway compression by means of mass effect, CHAOS poses a difficult problem for the clinical team during delivery. The EXIT procedure was developed as a solution to this problem: by preserving fetoplacental circulation throughout a scheduled cesarean section delivery, a safe fetal airway can be established before umbilical cord ligation (Fig. 49.3) (Harrison et al., 1996; Hirose et al., 2004). Infants with CHAOS still require postnatal airway reconstruction after delivery, but once a tracheostomy is in place, laryngeal or tracheal reconstruction is essentially an elective procedure and can be performed once the patient's overall status is optimized (Hirose et al., 2004). With EXIT, infants with CHAOS have a chance at survival with small case series showing promising results (Moldenhauer, 2013).

Disorders of the Mediastinum

In the posterior mediastinal space, thoracic neuroblastomas and neurenteric duplication cysts are the most common disorders encountered in the newborn. Bronchogenic cysts occur in the middle mediastinal space. An enlarged thymus and a mediastinal teratoma are the masses most often seen in the anterior mediastinum.

Thymus

The thymus occupies the upper anterior mediastinum, and it is more prominent in the newborn period than at any other time of life. It may be so large as to reach the diaphragm or obscure both

• **Fig. 49.3** Direct Laryngoscopy, Bronchoscopy, and Esophagoscopy Are Performed During an Ex Utero Intrapartum Treatment Procedure. Using these methods, airway obstruction can be overcome and endotracheal intubation can be performed. (From Hirose S, Farmer DL, Lee H, Nobuhara KK, Harrison MR. The ex utero intrapartum treatment procedure: looking back at the EXIT. *J Pediatr Surg.* 2004;39:375–380; discussion 375–380.)

cardiac borders on radiographs. The normal thymus can be distinguished from an abnormal mass by the absence of tracheal deviation or compression. The thymus changes in position with respiration and is less prominent with deep inspiration. It also involutes with stress as well as with corticosteroid therapy. Absence of the thymic shadow in an infant should alert the clinician to the possibility of severe combined immune deficiency syndrome or DiGeorge syndrome with hypocalcemia and cardiac anomalies (Collard et al., 1999).

The cardiophymic-to-thoracic ratio provides an index of thymic size. The shadow of the enlarged thymus is the most common radiopaque mass visualized in the anterior mediastinum of the newborn. The enlarged thymus causes little if any trouble in the neonatal period. Fletcher et al., as well as Gewolb et al. (1979), noted that a large thymus is present on the first day of life in infants at risk for hyaline membrane disease, presumably because of less-than-normal levels of glucocorticoids before birth (Fletcher et al., 1979). The effect that glucocorticoids have on the thymus is also supported by a study that found that prenatal steroid administration causes thymic atrophy (Michie et al., 1998). This steroid-induced atrophy, however, does not appear to have any clinical significance.

Congenital Mediastinal Teratoma

Mediastinal teratomas arise from primordial germ cells and are classified as being mature or immature. Mature teratomas are more common and contain all three embryonic cell layers (ectoderm, mesoderm, and endoderm). Immature teratomas are characterized by mature elements of all three germ layers but also have immature embryonic tissue interspersed (Thambi Dorai et al., 1998). Mediastinal teratomas rarely cause symptoms in the newborn infant. However, when an anterior mediastinal mass is associated with respiratory distress in the newborn, the strong likelihood is that the lesion is a mediastinal teratoma (Mogilner et al., 1992). Teratomas can also cause chest pain, cough, and recurrent post-obstructive pneumonia secondary to bronchial obstruction. Chest

• **Fig. 49.4** Bronchogenic Cyst. (A) The lateral film shows the trachea displaced anteriorly (arrow). (B) The anteroposterior film shows the barium-filled esophagus displaced to the right. (C) Another lateral film shows the barium-filled esophagus displaced posteriorly. (From Hope JW, Koop CE. Differential diagnosis of mediastinal masses. *Pediatr Clin North Am.* 1959;3:379.)

radiographs show an anterior mediastinal mass with calcification; however, CT and MRI are the primary modes of diagnosis. Mature teratomas are invariably not malignant, and surgical resection via median sternotomy, posterolateral thoracotomy, or thorascopy is sufficient treatment (Dulmet et al., 1993). Immature teratomas in children fortunately behave similar to mature teratomas and should be completely excised; however, there may be a role for chemotherapy before resection.

Prenatal diagnosis of a mediastinal teratoma is rare; however, large masses can cause compression of the mediastinum, leading to nonimmune hydrops and fetal demise (Sbragia et al., 2001). If hydrops does not occur and the pregnancy is carried to term, delivery can be complicated by airway compression and cardiopulmonary failure (Tsao et al., 2003a). These cases can be managed by in utero resection in the case of hydrops or via an EXIT procedure near term followed by resection after stabilization (Merchant et al., 2005).

Congenital Bronchogenic Cysts

Bronchogenic cysts arise from the foregut and are usually extrapulmonary. They can be located in the mediastinum (just above the tracheal bifurcation), pericardium, abdomen, neck, and within the diaphragm (Langston and Thurlbeck, 1986; Winters et al., 1997; Winters and Effmann, 2001). The minority of bronchogenic cysts are found within the lung, and some pathologists believe that these may not be distinct from intralobar sequestrations or type 1 congenital pulmonary airway malformations (CPAMs) (Stocker, 2009). Bronchogenic cysts can be seen on prenatal ultrasound, although they are more likely to present later as they increase in size over time, with airway compression, recurrent infection, hemoptysis, or pneumothorax (Langston, 2003). Intra-uterine airway compression can result in congenital lobar emphysema (CLE; see later discussion).

In the newborn, bronchogenic cysts are encountered infrequently, and most do not come to the attention of the practitioner until

later in infancy or during the second decade of life. Bronchogenic cysts seldom attain a large size and often contain clear fluid and debris. They are lined with columnar or cuboidal epithelium, and their walls generally contain smooth muscle, glands, and cartilage, the latter indicating their bronchial origin (Stocker, 2009). These cysts lie near the carina in the middle mediastinal space. They produce lung overdistension or atelectasis, depending on whether airway obstruction is complete or partial, and this is accompanied by respiratory distress in the newborn infant. Opsahl and Berman reported a case that showed overinflation on the left followed by clearing and then similar overinflation on the right (Opsahl and Berman, 1962). Radiographic examination often shows a mass lesion at or just above the carina and displacing the lower trachea forward (Fig. 49.4A). CT images show sharply marginated cystic masses of soft tissue or water attenuation, and specific criteria have been developed to distinguish these cysts from other mediastinal masses on CT (McAdams et al., 2000; Winters and Effmann, 2001). Barium swallow examination may reveal indentation of the esophagus, from external compression of the cyst pushing it backward at the level of the carina (see Fig. 49.4B–C). Bronchoscopy reveals compression of the trachea and sometimes of one major bronchus, usually from the posterior aspect. Sometimes a bronchogenic cyst may communicate with the airway and contain air. In the immediate newborn period, there may be retention of fetal lung fluid in the lung compromised by the bronchogenic cyst; the fluid may take days to clear. Treatment for bronchogenic cyst consists of surgical excision by partial or total lobectomy, with uniformly good results. Early excision prevents eventual development of symptoms in adulthood and malignant degeneration later in life (de Perrot et al., 2001; Jiang et al., 2015).

Neurenteric Duplication Cysts

These mediastinal cysts may be derived from the esophagus, stomach, or small bowel, so they may also be called enterogenous cysts.

Although they are not encountered frequently, they are far from uncommon in the newborn. They originate from duplicated segments of the foregut that have become partially or completely detached from the parent viscus. Neurenteric duplication cysts lie in the posterior mediastinum but with increasing size may project far into one or the other hemithorax. Their walls are composed of a mucosal layer, characteristic of their site of origin, and one or more muscular layers. They contain secreted fluid that is the same as that of their parent viscus; the fluid in a gastrogenic cyst contains pepsin and hydrochloric acid in the same concentration as in gastric juice.

The foregut becomes duplicated in the course of embryonic development by failure of complete resorption of primitive occluding epithelium, resulting in the formation of a supernumerary wall and eventually a separate lumen and cyst. The high percentage of vertebral anomalies associated with neurenteric duplication cysts led Veeneklaas to suggest that the primary embryonic defect lies in abnormal persistence of the primitive foregut adherence to the notochord (Veeneklaas, 1952). When the foregut descends from its early position in the neck, this adhesion to the notochord causes anomalies of the vertebral bodies. As the adhesion breaks off the duplicated portion of the foregut, it prevents complete descent into the thorax and abdomen along with the mature foregut.

Clinical signs depend on the size and location of the duplication cyst. Because all of these cysts are posterior and lie close to the trachea, esophagus, and great vessels, they are seldom present without signs of abnormality. Cyanosis, tachypnea, and dyspnea often are present from birth. Swallowing difficulties and vomiting are less frequent. Recurrent lower respiratory tract infections are findings in older infants with such cysts. Frank hemorrhage from the lungs or stomach is not uncommon. In most instances, hemorrhage indicates that the cyst is of gastrogenic origin, with peptic acid erosion into the trachea or esophagus. Technetium scans are useful for delineating cysts lined with gastric mucosa. Radiographs of the chest show abnormal densities that are often difficult to

distinguish from unusual cardiac contours. The barium swallow examination commonly shows displacement of the esophagus, usually forward because the mass is in the posterior mediastinum. The cyst may partially or totally compress the bronchus, with consequent lung overdistension or atelectasis. Sometimes the symptoms are intermittent as the cyst enlarges or empties. Bronchoscopy may show signs of external compression of the trachea or bronchus, usually from the posterior aspect. Superina et al. (1984) reviewed 25 years of experience with neurenteric duplication cysts and noted that a spinal component may accompany the mediastinal cyst in as much as 20% of affected children. They recommended careful radiographic evaluation of the spinal canal with CT scan and then excision of the intraspinal cyst, if possible, before the onset of neurologic signs in later childhood. The MRI scan may give improved delineation of intraspinal cysts (Azzie and Beasley, 2003). Operative resection is indicated as soon as the diagnosis of a neurenteric duplication cyst is made. It is neither necessary nor wise to delay exploration, because all intrathoracic masses will eventually become symptomatic and have been known to cause paralysis and fatal meningitis (Philippart, 1994).

Congenital Thoracic Neuroblastoma

Neuroblastoma, the most common solid tumor in the mediastinum of infants, arises from sympathetic neural tissue along the vertebral column and is therefore located in the posterior mediastinum. Neuroblastomas can arise anywhere in the sympathetic nervous system but most commonly occur in the adrenal gland. Thoracic neuroblastomas account for approximately 20% of cases (Grosfeld, 1999). They may extend into both lungs, causing respiratory distress, and they may extend into the spinal canal, later causing neurologic signs, including Horner syndrome and paralysis. The chest mass may be obvious on routine radiographs obtained for unrelated reasons in the newborn (Fig. 49.5) or on chest radiographs taken to evaluate significant respiratory distress (Li et al., 2001). In older

• **Fig. 49.5** Congenital Thoracic Neuroblastoma. The mass (arrow) is in the left upper hemithorax (A) and in the posterior mediastinum (arrow) (B). (From Hope JW, Koop CE. Differential diagnosis of mediastinal masses. *Pediatr Clin North Am.* 1959;6:379.)

infants the diagnosis may follow chest radiography for lower respiratory tract infection, or radiographs may be taken to investigate dyspnea with physical exertion. Approximately 80% of neuroblastomas will demonstrate tumor calcification on CT scan. While CT scan can aid in diagnosis, MRI is essential to assess the degree of intervertebral tumor extension, evaluate for lymphatic spread and chest wall involvement, and for discerning liver metastases (Slovic et al., 1997; Fraga et al., 2010). Diagnosis of thoracic neuroblastomas is also possible in the prenatal period as the fidelity of fetal ultrasound has improved (Moppett et al., 1999).

Despite some characteristic imaging findings specific to neuroblastomas, differentiation from other posterior mediastinal masses may be impossible before exploration. Invasion of neighboring lung parenchyma, however, strongly supports a diagnosis of neuroblastoma. Other clinical markers of neuroblastomas, including elevations of urinary vanillylmandelic acid and homovanillic acid, may be present, but this finding is less common in the newborn, and its absence does not rule out neuroblastoma. If the patient has systemic hypertension, plasma levels of epinephrine, norepinephrine, and dopamine may be elevated, but this has not been reported in a thoracic neuroblastoma. Also, results of assays for various clinical biologic markers may be positive; for example, serum ferritin and serum lactate dehydrogenase may be elevated, but this is not usual in the newborn. A bone marrow aspirate should be obtained for cytologic evaluation, and a nuclear bone scan should be performed to exclude the possible remote spread of metastases. A number of cytogenetic biologic markers may be detected in the excised tumor tissue (e.g., cellular DNA ditetraploidy, increased *N-myc* oncogene copy number); these usually indicate malignancy in older children (Ladenstein et al., 2001), but, again, they are commonly negative in the newborn.

Upfront surgical exploration is indicated for all benign tumors and should be pursued on low-risk stage I and II neuroblastomas, as excellent survival rates have been shown with surgery alone in these patients (Fraga et al., 2010; Strother et al., 2012). Intermediate risk stage III and IV neuroblastomas should be treated with adjuvant chemotherapy, with the goal of shrinking the tumor to allow for subsequent complete resection when able. Traditionally, these excisions have been done via open thoracotomy; however, with improvements in thoracoscopic technology, several groups advocate the use of video-assisted thoracoscopic surgery (VATS) for resection of thoracic neuroblastomas and report good results with no documented recurrences and with minimal complications (Fraga et al., 2012). While some worry about inadequate margins with VATS, the zoom magnification may improve visualization, making it easier and safer to resect large thoracic neuroblastomas. Patients with high-risk tumors, including those with disseminated disease or localized disease with *MYCN* amplification, should undergo multimodal therapy with high-dose chemotherapy and hematopoietic stem cell rescue, radiation, and surgical resection if indicated (Laprie et al., 2004).

The outlook for neuroblastomas in extra-adrenal locations is better than that for their adrenal counterparts (Young et al., 1970). The outlook for neuroblastomas manifesting in the first year of life also is good. Many of these tumors are cystic in nature, and the histologic examination suggests that the neuroblasts are arranged in clumps rather than in sheets; this “neuroblastoma in situ” feature carries a high likelihood of spontaneous regression and therefore a good prognosis. Most neuroblastomas in the newborn are Evans stage A, with a good outlook. So-called stage D (S) also is quite common (Moppett et al., 1999); although there are metastases to the liver, marrow, or skin, the prognosis is still good because

metastases to the bone are rare. The clinical markers are seldom elevated, and results of assays for the cytogenetic markers are seldom positive, all of which indicate a reasonable outlook. If the lesion can be completely removed and no bone metastases are found, then most infants survive. Some clinicians suggested that the chance of spontaneous regression is so high in the newborn that even surgery may not be necessary (Morgan, 1995; Li et al., 2001). However, intraspinal spread may occur, in which case the later clinical course is more troublesome, with paraparesis and neurogenic bladder (Moppett et al., 1999); most authors consider surgery to be advisable.

Disorders of the Chest Wall

Abnormalities of the bone and muscle of the chest wall may be a mechanical hindrance to ventilation.

Skeletal Disorders

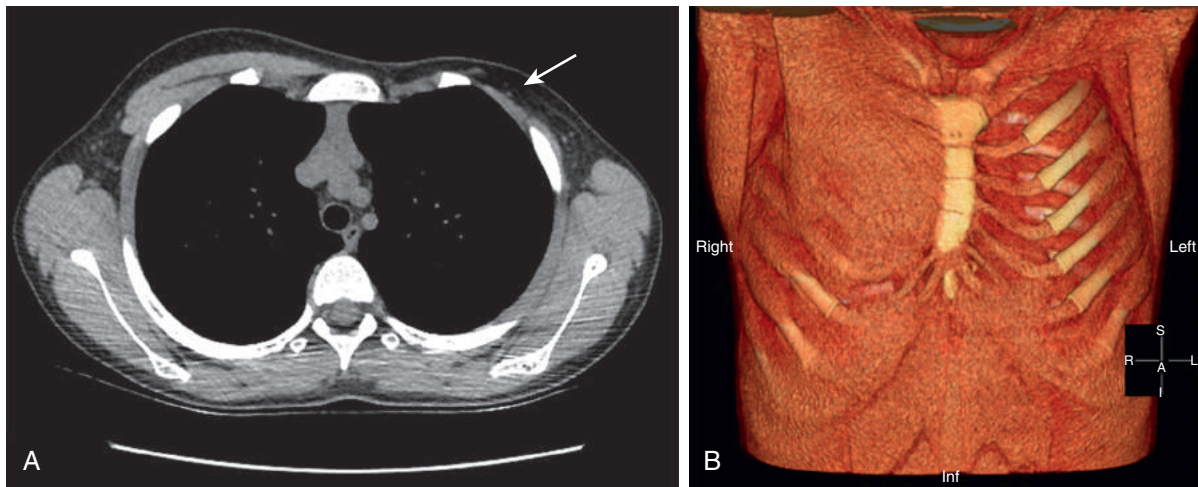

Although abnormalities involving bone are rare, they may be recognized immediately and are sometimes amenable to operative correction.

Defects of Sternal Fusion

Defects in fusion of the sternum are uncommon, occurring in less than 1 in 100,000 live births (Jabbad et al., 2010). Complete separation of the two halves of the sternum allows protrusion of cardiovascular structures, a condition known as *ectopia cordis* (Maier and Bortone, 1949). Lethal malformations of the heart are commonly associated with this condition. Upper sternal clefts are the most common type of sternal fusion defect (Shamberger and Welch, 1990). Early operation is advised to shield the underlying structures from injury, improve respiratory mechanics secondary to paradoxical chest motion, and because of the greater ease of approximating the separated parts in the first days of life compared with later (Sabiston, 1958). A lower sternal cleft and *ectopia cordis* with a congenital heart defect may be associated with congenital apertures in the upper abdominal wall, in the pericardium, and in the anterior diaphragm, with a Morgagni-type diaphragmatic hernia, the so-called pentalogy of Cantrell (Cantrell et al., 1958).

Pectus Excavatum

The most common sternal defect is pectus excavatum, occurring in 400 to 1000 live births (Fonkalsrud, 2009). It is characterized by a posterior curvature of the sternum and lower costal cartilages, resulting in a “funnel chest” appearance. Pectus is three to five times more common in males and is sometimes associated with Pierre Robin syndrome or Marfan syndrome. A family history of some type of anterior thoracic deformity was found in 37%–43% of patients (Shamberger et al., 1988; Nuss et al., 1998). Only approximately one-third of cases of pectus excavatum are present in infancy (Kelly, 2008). Even in those cases that are present at infancy, it is rarely a severe deformity, and symptoms are minimal. As the deformity worsens, the heart may be compressed between the sternum and the vertebral column and displaced to the left, impinging on the space of the left lung. This compression may result in exercise intolerance, chest pain, and shortness of breath (Nuss and Kelly, 2010). In addition to the physical symptoms, the chest deformity often leads to cosmetic concerns and psychological distress sufficient to warrant intervention. Although routine chest radiographs may suffice in evaluating the severity of chest wall deformity, chest CT is typically preferred because this modality

• **Fig. 49.6** Poland Syndrome. (A) Axial computed tomography (CT) scan and (B) three-dimensional CT reconstruction demonstrating a congenital absence of the pectoralis major and pectoralis minor muscle (arrow). There is no underlying rib deformity. (Courtesy of Dr. Chirag V. Patel, Assistant Professor, University of California, Davis Health System, Department of Radiology, Sacramento, CA.)

provides the bony and cartilaginous anatomic details as well as any information regarding cardiac compression necessary when considering surgical intervention. Using chest CT allows one to calculate the Haller index (HI), or the ratio of the transverse distance to the anteroposterior distance. A normal HI is about 2.5, and most cases of pectus excavatum that qualify for operative correction are greater than 3.25 (Haller et al., 1987). However, the indications for operative correction are debatable. Those patients with severe cardiac or pulmonary compression, abnormal cardiac or pulmonary function studies, or failed previous repairs are candidates for repair (Nuss and Kelly, 2010). Periodic evaluation of cardiovascular status with echocardiogram and electrocardiography in addition to assessment of pulmonary function is appropriate in the presence of progressive deformity and during periods of rapid growth such as adolescence. In our opinion, correction should not be undertaken until the child is several years of age and then only in those few children in whom the deformity appears to be progressing. Serial photographs are the best way to document changes in pectus excavatum. Results of both minimally invasive and open operative correction are excellent in the majority of patients; surgery is almost always associated with improved self-image and perceived functional activity (Kelly et al., 2008; Nuss, 2008; Fonkalsrud, 2009). Recurrences are possible during later active growth and may require repeat intervention, often with excellent outcomes (Sacco Casamasima et al., 2015).

Poland Syndrome

There is a great amount of diversity in the clinical manifestations of Poland syndrome; however, all children must have hypoplasia or absence of the pectoral muscles, typically only on one side. Additional manifestations include cartilage agenesis of the second through fifth ribs on the ipsilateral side, athelia, and amastia. There may be associated syndactyly, hemivertebrae, and scoliosis (Urschel, 2009). Breathing may be paradoxical and the cardiac impulse easily observed through the soft tissues, but there is rarely any severe respiratory distress that would necessitate emergent intervention. Later in childhood, although uncommon, there may be increasing respiratory symptoms with scoliosis-related lung disease and/or heart failure. CT scans are useful in assessing the configuration of the chest wall and its need for reconstruction when symptoms

develop (Fig. 49.6) (Bainbridge et al., 1991). No operative intervention is required in infancy, although complex reconstruction with autologous rib grafts, chest wall implants, and latissimus dorsi flaps may be desirable in later childhood as well as mammoplasty in affected girls after puberty (Haller et al., 1984; Hochberg et al., 1994).

Thoracic Dystrophies

Asphyxiating Thoracic Dystrophy (Jeune Syndrome)

A rare deformity of the thoracic cage in approximately 1 in 100,000 to 130,000 live births, asphyxiating thoracic dystrophy is an autosomal recessive chondrodystrophy, associated with short-limbed dwarfism and often polydactyly (Fig. 49.7). It was first described by Jeune et al. (1955). The ribs are horizontal, hypoplastic, and short, with flared costochondral junctions. The thorax is small, bell-shaped, and rigid; this results in displacement of the liver and spleen well into the abdominal cavity. Some degree of lung hypoplasia may be present and, if present, is often severe and lethal (Phillips and van Aalst, 2008). The pelvis shows flaring of the iliac wings and acetabular abnormalities (Kohler and Babbitt, 1970). Renal cystic dysplasia may be present, resulting in hypertension and renal failure. Prenatal diagnosis with ultrasonography is possible. In the past, most patients with this condition did not survive the first month. Oberklaid et al. (1977) studied 10 cases and noted that only 2 patients were alive at the time of the report: 1 of the 2 was in excellent health at 15 years of age. The more severely affected infants had respiratory distress from birth. Three patients have been described in one family; because it is an autosomal recessive trait, the expectation would be for an occurrence in 1 of 4 siblings, so mutations must be common. No parent–child occurrence has been described. Davis et al. (2001) reported an operative technique for lateral thoracic expansion in 10 patients with chest wall deformities limiting thoracic capacity—including 8 patients with classic Jeune syndrome. Three were younger than 1 year of age at the time of surgery, and 6 were ventilator dependent. All of the infants older than 1 year of age at the time of surgery improved, with measured lung volumes increasing in 2 of 3 studied and thoracic volumes by CT increasing in 4 of 5 studied. The only deaths were in 2 infants younger than 1 year of age at the time of surgery, suggesting that lateral thoracic expansion is a safe

• **Fig. 49.7** Asphyxiating Thoracic Dystrophy. On (A) anteroposterior and (B) lateral views of the chest, the thoracic dimension is seen to be reduced in comparison with the abdominal dimension. (C) Radiograph of the pelvis shows flaring of the iliac crests and bony protrusions of the acetabulae. (A and B, Courtesy of Dr. John Kirkpatrick; C, from Avery ME, Fletcher BD, Williams RG, *The Lung and Its Disorders in the Newborn Infant*. 4th ed. Philadelphia, PA: WB Saunders; 1981.)

and effective procedure for patients beyond the first year of age. A vertical expandable prosthetic titanium rib procedure has also been introduced for the purpose of progressive expansion of the chest cavity in patients with thoracic insufficiency (Waldhausen et al., 2007). However, long-term improvements in lung function, specifically in patients with Jeune syndrome, have yet to be reported (Phillips and van Aalst, 2008).

Other Thoracic Dystrophies

Severe underdevelopment of the thoracic rib cage, accompanied usually by lethal pulmonary hypoplasia, may be seen in other conditions, such as thanatophoric dwarfism syndrome, short rib–polydactyly syndrome, and camptomelic dwarfism syndrome. Affected infants do not usually survive for long after birth.

Neuromuscular Disorders

Other causes of thoracic dysfunction are diseases of the nerves and muscles, including congenital myasthenia gravis, congenital spinal muscular atrophy (Werdnig–Hoffmann disease), congenital myotonic dystrophy, glycogen storage diseases, and congenital spinal injury. Such conditions are usually recognized in the context of the associated systemic muscular weakness. Newborns with myasthenia gravis have episodes of muscle weakness, poor feeding, weak cry, hypoventilation, and apnea with a positive response to an anticholinesterase medication. In congenital spinal muscular atrophy, there is lung hypoplasia associated with absent fetal breathing, and as a result the thorax is small. Other features include severe hypotonia, muscle fasciculation, respiratory failure, and

early death; the inheritance is autosomal recessive. In congenital myotonic dystrophy, there is lung hypoplasia from absent fetal breathing; affected infants have respiratory distress at birth, rapidly need mechanical ventilation, and are soon ventilator dependent. Mothers of these infants have myotonia, difficulty in relaxing muscle contractions; the inheritance is autosomal dominant.

Disorders of the Pleural Cavity

The pleural cavity lies between the parietal pleura, lining the chest wall, and the visceral pleura, lining the lung and other structures. The blood supply to both pleural surfaces is systemic. Venous drainage of the parietal pleura is to the systemic system and the visceral pleura to the pulmonary system. The pleural surfaces filter fluid into the pleural space and the pleural lymphatics then resorb fluid from the pleural cavity (Wiener-Kronish et al., 1985). This process is hindered in the setting of abnormal lymphatic development or abnormal systemic venous pressures (because the thoracic lymphatic system drains directly to the systemic veins), resulting in chylothorax. Chylothorax can also occur as a result of surgical disruption of the thoracic duct or in the setting of lymphatic malformations. Other causes of hydrothorax in the newborn include hydrops fetalis, transudative pleural effusions associated with congenital lung lesions or group B streptococcal pneumonia, empyema (usually associated with nosocomial pneumonia), or fluid extravasation from a displaced central venous catheter.

Congenital Chylothorax

The prenatal diagnosis of an isolated pleural effusion without an associated thoracic malformation or hydrops fetalis is most likely to be a chylothorax—or lymphatic effusion, because chyle cannot be present in the absence of fat-containing enteral feeds (Beghetti et al., 2000). A large fetal chylothorax may evert the diaphragm and can be the cause of hydrops fetalis, probably because of hypoproteinemia or impaired venous return in the setting of increased intrathoracic pressure. Fetal chylothorax portends a worse prognosis for survival if it is bilateral or associated with hydrops, and prognosis is better if the effusion resolves without reaccumulation (Longaker et al., 1989). Large fetal chylothoraces can result in pulmonary hypoplasia. In utero intervention may be undertaken in cases of large or bilateral effusions, or hydrops, and has been shown to improve survival (Lee et al., 2016). Classically, these interventions include transabdominal thoracentesis (with ongoing ultrasound monitoring for fluid reaccumulation) and placement of an indwelling thoracoamniotic shunt (if the effusion reaccumulates), to allow continued drainage of fluid. More recently, in utero pleurodesis has been successfully performed using Picibanil (OK-432); however, long-term effects of this therapy are unknown (Yang et al., 2012). Fetuses diagnosed with chylothorax should be evaluated for associated conditions that may affect their prognosis, including Down syndrome, Noonan syndrome, and Turner syndrome.

Newborns with congenital chylothorax often present with severe respiratory distress, requiring immediate respiratory support and urgent drainage of pleural fluid. Chest radiographs will show either unilateral or bilateral fluid accumulation, often with shift of the mediastinum. Aspiration of the fluid can confirm the diagnosis. Before feedings have been started, the fluid will be straw colored but will change to the classic milky-white appearance after feedings have been initiated. Characteristics of a chylous aspirate include a high cell count with a lymphocytic predominance, a high

TABLE 49.1 Characteristics of Chylous Effusions

| Characteristic | Description |
|-----------------------|--|
| Appearance | Clear yellow (milky with fat-containing feeds) |
| Cell count | >1000 cells/mm ³ |
| Lymphocyte proportion | >80% |
| pH | 7.4–7.8 |
| Triglycerides | >110 mg/dL |
| Cholesterol | 65–220 mg/dL |
| Albumin | 1.2–4.1 g/dL |
| Total protein | 2.2–5.9 g/dL |

Adapted from Rocha G. Pleural effusions in the neonate. *Curr Opin Pulm Med.* 2007;13:305–311.

triglyceride level (usually above serum levels, but not present unless enteral feeds initiated), and high protein content (Table 49.1). The introduction of small-volume fat-containing feeds with resultant elevated fluid triglyceride levels can confirm the diagnosis if biochemical indices are otherwise not confirmatory. A review of 39 cases of pediatric chylothorax revealed that the composition was consistent with previously described classic characteristics (Buttiker et al., 1999). Total cell counts were greater than 1000/mm³ in 92% of cases, and 85% of effusions had greater than 90% lymphocytes (range 57%–89% in 6 additional children). Fluid triglyceride levels were greater than 1.1 mmol/L (98 mg/dL) in all but one case, with values ranging from 0.56 to 26.6 mmol/L (50 to 2358 mg/dL).

Management of Chylothorax

Neonatal management of a congenital chylothorax includes replacement of protein, clotting factors, and immunoglobulins as needed. Ongoing respiratory support may be needed, and often a chronic chest drain is required to decrease respiratory compromise. Feeds are usually restricted, either providing medium-chain triglycerides (MCTs) only (because MCTs are generally absorbed directly from the intestine without processing to chylomicrons) or a nonfat diet. If these measures fail, a period of total enteric rest is undertaken, with parenteral nutrition administered, until resolution of the chylous effusion. Some practitioners believe that a period of enteric rest is necessary to decrease strain on the lymphatic system, because lymphatic efflux is still increased even with nonfat-containing diets (Le Coultré, 2003). Once chest drainage has resolved, feeds are reintroduced with a MCT-only formula for 3 to 6 weeks before transitioning to a normal diet.

There are no controlled studies demonstrating that one strategy is superior to others to hasten resolution of chylothorax, and in one series, 50% of pediatric chylothoraces resolved with MCT-only diets (Le Coultré et al., 1991). A later series from the same institution had 80% (41 of 51) resolution with conservative, nonoperative management (MCT-only diet or enteric rest) up to 4 weeks' duration (Beghetti et al., 2000). The primary risk of this approach is infection, because these children have prolonged hospitalizations with central venous access, chest drains, no enteral feeds, and protein and immunoglobulin losses. Eight of 51 children had severe infections in this series. Children who were less likely to have spontaneous

resolution of chest drainage included those children with elevated central venous pressure, children who had more prolonged effusions, and children with higher output than those with surgical injury. There were more frequent operative interventions in this group (6 of 14 children), which were undertaken only if 4 weeks of conservative therapy failed to decrease drainage to less than 10 mL/kg per day (Beghetti et al., 2000). In one series, 4 of 11 children with drainage after 4 weeks resolved their chylothorax by 6 weeks, with 2 of the remaining children too unstable to undergo surgical intervention (Buttiker et al., 1999).

An adjunctive medical approach is the administration of somatostatin or its analogue, octreotide, to decrease pleural drainage. Somatostatin is delivered only via continuous infusion, whereas octreotide can also be given via intermittent subcutaneous injection, because of its longer half-life. The mechanism of effect is thought to be via decreased intestinal secretions and absorption and therefore intestinal efflux and abdominal lymphatic return (Kalomenidis, 2006). Some practitioners proceed quickly to the use of these medications, believing they decrease the volume and duration of chest drainage compared with conservative management; however, this has not been studied in a controlled setting, so the efficacy and risks of this approach are unknown (Das and Shah, 2010). Others use these medications once conservative measures have failed. Potential risks of therapy include hormonal effects of glucose instability and hypothyroidism and gastrointestinal (GI) effects such as cholelithiasis, hepatocellular injury, nausea, diarrhea, abdominal distention, and decreased intestinal perfusion. In this regard, monitoring of serum glucose, thyroid function, liver enzymes, and indicators of cholestasis during therapy is recommended. These serious side effects raise concerns, particularly regarding concomitant feeding during administration of the medications. Dosing is either titrated up until chest drainage is minimal (typically starting at 3.5 µg/kg per h and advancing in several steps to 10 µg/kg per h) or started at the higher dose and titrated down once drainage has abated (Helin et al., 2006; Roehr et al., 2006). The infusion is usually continued for several days after chest drainage is controlled and then weaned off over several days. Outcomes using octreotide for congenital chylothoraces have been promising, with several case reports and a recent small case series demonstrating resolution of the chylothorax without adverse effects (Bulbul et al., 2009; Shah and Sinn, 2012). There are reports of recurrence after discontinuation of the medication (Roehr et al., 2006).

Most practitioners recommend about 3 to 4 weeks of maximal medical therapy, before proceeding with an operative intervention, while others recommend intervention in patients who drain more than 100 mL/year of age per day without slowing down after 10 to 20 days (Buttiker et al., 1999). Effusions are unlikely to resolve after 6 weeks, and waiting too long for operative intervention may result in significant compromise to the child. Operative interventions include thoracic duct ligation via thoracotomy or thoracoscopy, pleurodesis, and/or placement of a pleuroperitoneal shunt (Buttiker et al., 1999; Clark et al., 2015; Resch et al., 2016).

Congenital Thoracic Masses and Cysts

Fetal lung masses vary in the degree of abnormality of parenchyma and vasculature and probably represent a spectrum of developmental abnormalities that may be difficult to distinguish prenatally (Langston, 2003; Ankermann et al., 2004). In fact, some investigators have suggested classifying these lesions solely on the basis of the vascular supply (systemic vs pulmonary) and whether or not lung structure is normal (Achiron et al., 2004), because the histology

and probably the developmental pathways leading to the individual lesions are overlapping. Some level and degree of fetal airway obstruction have been implicated as the cause of many of these lesions (Langston, 2003). In prenatal series, CPAMs of the lung are frequently the most common lesion reported (Achiron et al., 2004). However, in postnatal series, CPAMs are often less common (with various imaging modalities and pathology available to clarify the diagnosis after birth), particularly when only cystic lesions are considered (Winters and Effmann, 2001; Langston, 2003; Stocker, 2009). There are multiple reports of “hybrid” lesions, with features of both CPAM and bronchopulmonary sequestration (BPS), emphasizing that these lesions constitute a spectrum of anomalies (Winters and Effmann, 2001; Langston, 2003).

Congenital Pulmonary Airway Malformation of the Lung

CPAMs are the most common congenital lung lesions and develop from an overgrowth of abnormal lung tissue, extending from different levels of the airway. In general, they are unilateral. The lesions may communicate with the airways, allowing them to transition from being fluid filled in utero to air filled postnatally, but they do not contain normal alveoli. CPAMs were previously known as congenital cystic adenomatoid malformations (CCAMs), which were originally classified into three types based upon the size of the cysts and their cellular characteristics (Stocker et al., 1977). Subsequent revisions of this classification system have included less common proximal and distal lesions and have suggested new nomenclature based on the fact that not all lesions are either adenomatoid or cystic. The term “congenital pulmonary airway malformation” (CPAM), initially proposed by Stocker, has now become the accepted terminology for these lesions (Stocker, 2002). Table 49.2 shows the stages of lung development with the corresponding airway malformation and CPAM type. Consistent with this classification, persistent epithelial expression of the nuclear regulatory protein thyroid transcription factor 1 has been found in type 1 and 3 CPAMs (see later discussion), indicating developmental arrest in the pseudoglandular stage (Morotti et al., 2000), and targeted fetal airway overexpression of the growth factor fibroblast growth factor 10 in rats produces CPAM-like lesions (Gonzaga et al., 2008).

Congenital Pulmonary Airway Malformation Types

Type 0 CPAMs originate from the tracheobronchial tree. There is normal lung lobulation, but no formation of alveoli (Stocker, 2002). There are only bronchial-like structures present, indicating an arrest of development in the pseudoglandular stage (Davidson et al., 1998). Lungs may be normal weight or small, but, regardless, this lesion is rapidly lethal because of severe, intractable respiratory failure. The lesion has been termed *acinar dysplasia* (Rutledge and Jensen, 1986). It is diffuse and bilateral, recurs in families, and can be associated with other anomalies, suggesting a genetic cause (Moerman et al., 1998; Gillespie et al., 2004). In a large pathology series, fewer than 2% of the pulmonary airway malformations were characterized as acinar dysplasia (Stocker, 2002).

In contrast, type 1 CPAMs are the most common lesion in postnatal series of airway malformations, identified in 60%–65% of cases (Stocker, 2002, 2009). Cysts are large, usually greater than 2 cm, limited in number, and originate from the distal bronchi or proximal bronchioles (Fig. 49.8A–C). The cysts usually communicate with each other, and they may decrease in size as they drain progressively during advancing gestation. Postnatally, they are aerated, with

**TABLE
49.2****Stages of Airway Branching and Lung Development With Corresponding Congenital Airway Malformation**

| Developmental Stage | Developmental Events | CPAM TYPE | |
|-------------------------------|---|---|-------------|
| | | Stocker | Adzick |
| Embryonic 0–7 weeks | Formation of tracheal bud and growth and branching to segmental bronchi | Type 0 Tracheobronchial Type 1 Bronchial/bronchiolar | Macrocytic |
| Pseudoglandular 7–17 weeks | Completion of airway branching to terminal bronchioles (preacinar); gland formation | Type 2 Bronchiolar | |
| Canalicular 17–27 weeks | Formation of respiratory bronchioles to prealveolar structures | Type 3 Bronchiolar/alveolar duct | Microcystic |
| Saccular 28–36 weeks | Formation of secondary septae | Type 4 Distal acinar | |
| Alveolar 36 weeks–2 years | Formation of alveoli | | |

CPAM, Congenital pulmonary airway malformation.

• **Fig. 49.8** Congenital Pulmonary Airway Malformation. (A) Chest radiograph of an asymptomatic child with a prenatally diagnosed congenital pulmonary airway malformation (CPAM) in the left upper lobe (arrow). (B, C) Axial and coronal computed tomography (CT) images demonstrate a single 3.1 × 2.7-cm cystic lesion in the left upper lobe consistent with a type 1 CPAM. The child underwent uncomplicated left upper lobectomy at 3 months of age. (D) A chest radiograph of an infant with a prenatally diagnosed CPAM that had rapid enlargement of the cystic component, resulting in mediastinal shift and acute respiratory compromise, is shown. (E, F) Axial and coronal CT images show a multicystic mass with cysts ranging from a few millimeters to 1.5 cm consistent with a type 2 CPAM. In the operating room, the patient was found to have a multicystic lesion confined to the left upper lobe with compressive atelectasis of the left lower lobe and underwent left upper lobectomy. (Courtesy of Dr. Chirag V. Patel, Assistant Professor, University of California, Davis Health System, Department of Radiology, Sacramento, CA.)

fluid also present in some lesions. Type 1 CPAMs are restricted to a single lobe in 95% of the cases. Bilateral lesions are rare. The lesions are lined by a spectrum of respiratory epithelial cells, ranging from cuboidal to ciliated pseudostratified columnar epithelium, and mucus-producing cells may occur in gland-type tissue. The walls of the lesions may resemble walls of bronchi. Respiratory distress depends on the size of the lesion, with some lesions detected only by incidental imaging or following infection or malignant transformation. There does appear to be a risk of malignant transformation in unresected or residual CPAM tissue. The specific link to neoplasm has not been elucidated, though the diagnosis of bronchoalveolar carcinoma (BAC) is made in relatively young patients (10–42 years), and a spectrum of malignancy has been described (MacSweeney et al., 2003; Mani et al., 2007). This is the only CPAM type that is associated with malignancy, and the young age of affected patients suggests that the CPAM lesion is the cause of the malignancy (MacSweeney et al., 2003).

Type 2 CPAMs are characterized by multiple, smaller macroscopic cysts, 0.5–2 cm in diameter, which may not be evident by chest radiograph (see Fig. 49.8E–F). These lesions account for 15%–20% of CPAMs. The cysts are lined by respiratory epithelial cells, ranging from cuboidal to columnar in morphology and appear as multiple bronchiole-type structures, although intra-acinar structures may also be interspersed (Rosado-de-Christenson and Stocker, 1991). These lesions are most commonly associated with other anomalies, in 50% of cases, which include severe bilateral renal dysplasia or agenesis, agenesis of other genitourinary structures, sirenomelia, extralobar pulmonary sequestration, and diaphragmatic hernia (Stocker et al., 1977; Stocker, 2009). Conotruncal cardiac malformations have also been described in association with type 1 and type 2 CPAMs (Stocker et al., 1977; Hüsler et al., 2007), and ventricular septal defects have been diagnosed in fetuses and infants with all CPAM types.

Type 3 CPAMs are uncommon lesions, occurring in 5%–10% of CPAM cases (Stocker, 2002). These lesions are generally solid, with microscopic cysts (although single larger cysts can be present), and involve an entire lobe or the entire lung. There is often a mass effect in the thorax, and the lesions can cause lung hypoplasia through compression of adjacent structures. The lesions themselves contain bronchiolar and alveolar duct-type morphology with cuboidal epithelium, and there are alveoli-like structures.

Type 4 lesions have been more recently described and account for 10% of CPAMs (Stocker, 2002). With large cysts (maximum diameter 7 cm) present, some of these lesions may be mistaken for type 1 CPAMs. They are usually confined to one lobe and tend to be peripheral in location. Infants and children may present with mild respiratory distress, or more severe symptoms if pneumonia occurs, or if the lesion ruptures, causing pneumothorax. However, type 4 CPAMs can also be detected by incidental imaging. These lesions are lined with type I alveolar (flat) and type II (rounded) epithelial cells. The presence of substantial portions of cells representing the more proximal areas of the lung should raise suspicion for pleuropulmonary blastoma (PPB), a distinction that is important (because of malignancy associated with PPB; see later discussion), but one that can be difficult.

The approach to diagnose CPAMs in utero has led to a different classification system, based on the natural history of these fetal lesions (see later discussion). Macroscopic CPAMs are defined when a lesion contains cysts that are greater than or equal to 5 mm (types 1 and 2 CPAMs), and microcystic CPAMs are defined as a solid lesion, with cysts less than 5 mm (type 3 CPAMs) (Adzick et al., 1985). Some lesions categorized by these criteria on fetal

ultrasound have been diagnosed as BPS after postnatal resection (Davenport et al., 2004).

Fetal Diagnosis and Natural History

Fetal diagnosis of a CPAM is often made when mediastinal shift because of mass effect from the lesion is identified and a cystic, intermediate, or solid mass is detected. This may occur during routine fetal ultrasonography or when the mother is referred for evaluation of polyhydramnios (thought to occur when the mass compresses the esophagus and thus limits fetal swallowing) (Adzick, 2009). A systemic vascular supply identified on imaging is more consistent with a diagnosis of BPS (Winters and Effmann, 2001). Fetal MRI can be used to help distinguish a CPAM from other pulmonary pathology, including BPS and congenital diaphragmatic hernias. In a recent population-based study from the United Kingdom, confirmed CPAMs (postnatal or postmortem) occurred in 9 per 100,000 births, without accounting for lesions that were not further investigated secondary to prenatal resolution (Gornall et al., 2003). In this study, 57% (21 of 37) of fetal CPAMs were confirmed, and 5 cases were missed (prenatal detection rate 21 of 26 [81%]). Generally, growth of CPAM lesions increases until about 28 weeks' gestation, after which time it plateaus and the lesion regresses in size while the fetus continues to grow (Kunisaki et al., 2007a; Adzick, 2009). Fetal and neonatal problems that arise as the result of a CPAM include the development of nonimmune hydrops and lung hypoplasia, which may be due to compression of the otherwise normally developing lung. Up to one-third of fetuses with a CPAM develop hydrops (Adzick et al., 1998). Factors associated with the development of nonimmune hydrops include an everted ipsilateral hemidiaphragm, predominantly cystic lesions, lesions that exist into the third trimester, and lesions with a CPAM volume ratio (CVR) greater than 1.6 (Vu et al., 2007). The CVR calculates the volume of the mass ($\text{length} \times \text{weight} \times \text{height} \times 0.52$) divided by the head circumference. With a CVR greater than 1.6, 75% (12 of 16) of fetuses developed hydrops, while only 17% of those with a CVR less than or equal to 1.6 (7 of 42) developed hydrops (Crombleholme et al., 2002). In a series evaluating fetal macrocystic and microcystic lesions, generally the fetuses with microcystic lesions had poorer outcomes, with intrauterine demise or early neonatal death (Adzick et al., 1985). Compared with normal lung, CPAM lesions have unregulated growth, with increased proliferation and decreased apoptosis (Cass et al., 1998), although they are relatively hypovascular (Cangiarella et al., 1995). In fetal CPAM tissue, increased Platelet-Derived Growth Factor subunit B (PDGF- β) and decreased fatty acid binding protein-7 expression have been detected (Liechty et al., 1999; Wagner et al., 2008).

Prenatal Management

Initial ultrasound evaluation of the fetus with possible CPAM should include assessment of lesion size with relevant indices, vascular supply, degree of mediastinal shift, ipsilateral diaphragmatic conformation (normal, flat, or everted), polyhydramnios, placentalomegaly, and the presence of any other fluid collections (ascites, integumentary edema, pleural or pericardial effusion) indicating the development of fetal hydrops. Additional prenatal evaluation of a fetus with a known CPAM should include a full fetal survey to identify other anomalies, a karyotype, and an echocardiogram, to evaluate for congenital heart disease and to assess cardiac inflow patterns and outputs. These cardiac indices may help identify impending hydrops, mandating closer ultrasound follow-up and repeated echocardiographic measurements. Most referral centers

recommend at least weekly follow-up ultrasound examinations evaluating lesion size and monitoring for development of hydrops until 28 to 29 weeks' gestation, at which point regression of the lesion should be occurring. Thereafter, ultrasound evaluations can be spread out to every 2 weeks. Some referral centers have advocated twice-weekly surveillance if the CVR is greater than 1.6, until 28 weeks' gestation (Adzick, 2009). In a recent series, 21 of 54 fetal lung masses decreased in size or resolved by delivery (Davenport et al., 2004), and a similar proportion of fetal CPAM cases were not detectable at birth in a population-based study (13 of 37, 35%) (Gornall et al., 2003).

The diagnosis of hydrops in a fetus with CPAM portends a poor prognosis, with either fetal demise or preterm delivery of a compromised infant (Gornall et al., 2003; Grethel et al., 2007; Kunisaki et al., 2007a). Thus impending or definite hydrops is an indication for fetal intervention. The specific intervention depends on the type of lesion. In fetuses with a macrocystic CPAM, a growing, dominant cyst, and impending or definite hydrops, placement of a thoracoamniotic shunt results in a decrease in cyst size and hemodynamic improvement, with relatively good neonatal survival (12 of 16 in two series) (Adzick et al., 1998; Wilson et al., 2004). However, shunt placement at less than 21 weeks' gestation may be associated with chest wall deformity, which can compromise later respiratory function, so other interventions may need to be taken at that early gestation (Merchant et al., 2007). Fetal thoracentesis is rarely effective as definitive treatment, because cyst fluid invariably reaccumulates, but it might serve as a temporizing measure until further treatment can be undertaken. For fetuses with impending hydrops and a microcystic CPAM (or failed decompression of a large cyst), open fetal resection (lobectomy or pneumonectomy) improves the chances of survival, although mortality remains high (10 of 23 in one series), and nonsurvivors tended to be more premature (Grethel et al., 2007). This selected approach to fetal resection has resulted in resolution of hydrops and mediastinal shift in survivors (Adzick, 2009). For fetuses greater than 32 weeks' gestation, or in the case where fetal surgery is contraindicated because of preterm labor, an EXIT-to-resection procedure may provide a chance for survival (Grethel et al., 2007; Adzick, 2009). EXIT procedures have also been undertaken in later-gestation fetuses with persistent large lesions (mean CVR 2.2) despite other fetal interventions, although the impact of this strategy on survival and other outcomes is unknown (Hedrick et al., 2005; Adzick, 2009).

Before undertaking any fetal intervention, prenatal glucocorticoid therapy to accelerate fetal lung maturation should be administered. This practice, utilizing betamethasone (12 mg intramuscularly every 24 h \times 2 doses), led to the observation that fetuses with microcystic CPAMs (type 3) and hydrops resolved their hydrops after betamethasone exposure (Tsao et al., 2003b). In this series, three fetuses with mild-to-moderate hydrops treated at 21 to 26 weeks' gestation avoided further fetal interventions, were delivered at term, and survived. This observation led to subsequent studies comparing the use of steroids with open fetal surgery in fetuses with macrocystic CPAMs that demonstrated the effectiveness of steroids in not only halting further growth of a CPAM but also causing regression (Peranteau et al., 2007; Loh et al., 2012). Since this discovery, steroids have become the first line of treatment in fetuses with large microcystic CPAM lesions.

Postnatal Management

In fetuses that do not develop hydrops, the overall prognosis is good and probably depends on the type of lesion and the presence

of other anomalies. Generally, the prognosis of a type 1 CPAM is good, particularly if fetal intervention is not required. Following resection, there is usually resolution of any symptoms associated with the lesion. Type 2 CPAMs have a worse prognosis, because of the association with additional serious malformations. Type 3 CPAMs are thought to be uniformly lethal from their earliest descriptions and can be associated with lung hypoplasia (Stocker et al., 1977). For fetuses with large microcystic CPAMs, fetal resection, if indicated, may mitigate hypoplasia. However, case series have described substantial spontaneous regression of microcystic CPAMs, with an increased rate of in utero resolution compared with macrocystic lesions (Davenport et al., 2004). In a large series from a single referral center, neonatal survival was 98% (118 of 121) (Grethel et al., 2007). Five infants underwent fetal procedures, with 1 death, and there were 2 neonatal deaths. In a population-based series, there were no postnatal deaths following 20 live births, with a single intrauterine fetal demise and 5 terminations (Gornall et al., 2003). Three fetal interventions (thoracentesis or thoracoamniotic shunt placement) were undertaken in these patients.

Approximately 75% of newborns with a prenatally diagnosed CPAM are asymptomatic at birth (Parikh and Rasiah, 2015). The remainder may present with respiratory distress with or without pulmonary hypertension, which can be severe enough to require ECMO support (Kunisaki et al., 2007a; Adzick, 2009). The likelihood of respiratory distress is best predicted by a CVR of greater than 0.84, and the severity of the respiratory distress usually increases as the size of the CPAM increases (Ruchonnet-Mettrailler et al., 2014). However, even in a series of large fetal CPAMs (at least 3 cm \times 3 cm), only 4 of 9 infants had respiratory distress requiring resection in the first week of life. For newborns with prenatally diagnosed CPAMs, lesions may be detected on chest radiograph, as solid masses, or fluid or air-filled cysts. Mediastinal shift, mass effect, or areas of air trapping due to airway obstruction may be appreciated. Some centers use ultrasound as an adjunctive modality in the neonatal period, but many surgeons prefer a CT scan as the definitive imaging study, which also can detect lesions that are no longer present on fetal ultrasound (Winters and Effmann, 2001). CT scans can also determine if there are multiple bronchopulmonary malformations, which may also require resection, and the use of intravenous contrast allows for definition of the vascular supply, helping to differentiate CPAMs from BPS (Johnson and Hubbard, 2004). For asymptomatic newborns, surgeons will often defer this study until several months of age, because surgical resection is also deferred. The usual surgical approach is lobectomy for the majority of lesions confined to a single lobe. More diffuse lesions might require bilobectomy or pneumonectomy. These surgical approaches are likely to result in the removal of normal lung but may also decrease the risk of air leak and infection after resection (Shanmugam, 2005), and compensatory lung growth does occur after lobectomy (Nakajima et al., 1998). Additional postoperative complications may include prolonged pleural effusion, pneumothorax, pneumonia, and wound infection (Waszak et al., 1999; Kim et al., 2008).

The need for resection in asymptomatic newborns remains controversial, and there is no consensus on this topic (Aziz et al., 2004; Singh and Davenport, 2015; Stanton, 2015). Those who argue for watchful waiting cite the risks of surgery and anesthesia, the overtreatment of "nondisease," and a lack of evidence of the associated malignancy risk as factors for not resecting asymptomatic lesions. Those who argue for intervention say that resection prevents complications of disease, including the risk of malignancy, the

psychological benefit of removing the lesion, and the improvement in lung volume after resection. In a national survey of Canadian pediatric surgeons, there was not even consensus on whether to resect asymptomatic lesions or not between different surgeons within individual centers (Lo and Jones, 2008). The majority of respondents in this survey (67%) endorsed resecting asymptomatic lesions present on CT, with 78% selecting 2 to 12 months as the age for operation. The concerns about not resecting a lesion are that it remains a persistent nidus for lower respiratory tract infection and that there is the potential for malignant transformation. However, the latter concern is confined to type I CPAMs. A similar study done in the UK found that 24% of surgeons never resect asymptomatic lesions, while 20% always do (Peters et al., 2013).

Generally, children who have undergone resection for CPAMs are healthy. Pulmonary function data demonstrate normal vital capacity, residual volume, and expiratory flows between 1 and 2 years post lobectomy (Nakajima et al., 1998). There are some reports of reactive airway disease and lower respiratory tract infection (Kunisaki et al., 2007a) and, in more severely affected children, chronic lung disease and pulmonary hypertension (Keller et al., 2006; Kunisaki et al., 2007a).

Bronchopulmonary Sequestration

Bronchopulmonary sequestrations are rare congenital malformations consisting of nonfunctional lung parenchyma that does not have a normal connection to the tracheobronchial tree (Rosado-de-Christenson et al., 1993). The lesions have a systemic arterial supply. Sequestrations are categorized into *extralobar* sequestrations, which are lesions that have their own pleural investment and systemic (80% of the time) venous drainage (and are therefore separate from the lung), and *intralobar* sequestrations, which are integral to the lung pleura and drain via the pulmonary venous system. Intralobar lesions usually require lobectomy for removal, because they are invested within the lung. The origin of an intralobar sequestration is somewhat controversial. Some experts believe it is not a congenital lung lesion but is rather always acquired after lung infection and injury, because inflammation, fibrosis, and cystic degeneration are its primary pathologic features (Frazier et al., 1997). In a large pathologic series, intralobar lesions usually diagnosed in adulthood and presenting as lower respiratory tract infection account for about 75% of BPS. Others believe that intralobar sequestration can be congenital in origin but is relatively rare in that setting when compared to extrapulmonary sequestration (Winters and Effmann, 2001). Thus the remainder of this discussion focuses on extralobar sequestration.

Extralobar sequestrations probably originate as an independent bud from the foregut that derives its blood supply from splanchnic vessels (Rosado-de-Christenson et al., 1993). Usually the connection to the foregut is lost during development, although some lesions have persistent connections to the esophagus or the stomach (also referred to as bronchopulmonary foregut malformations). As accessory lobes, they occur within both the thorax and abdomen. Hybrid lesions with features of both a CPAM and a sequestration can occur (Lopoo et al., 1999; Winters and Effmann, 2001). Extralobar sequestrations are usually situated on the left side (65%–90%), with the most common location between the lower lobe and the hemidiaphragm (approximately 70% of cases). Extrapulmonary BPS can also occur in the abdomen, the mediastinum, the pericardium, and the diaphragm itself. It is more common in males than females (3 to 4:1 ratio), and it also commonly occurs in association with other anomalies, including foregut duplication cysts, bronchogenic cysts, CPAMs, pericardial

defects, and ectopic pancreas. In addition, approximately 5% of children with a congenital diaphragmatic hernia will have extralobar sequestration. Histologically, these lesions appear as normal lung, except with dilated airway structures and, commonly, lymphangiectasia. A normal-appearing bronchus is present about 50% of the time. Associated pleural effusions are not uncommon (up to 10% of fetal BPS) and may be secondary to torsion of the vascular pedicle with resultant venous obstruction and elevated pressure or lymphatic abnormalities (Hernanz-Schulman et al., 1991; Johnson and Hubbard, 2004).

Fetal diagnosis of intrathoracic BPS is suspected when there is an echogenic mass, which may also contain cysts. Depending on its size, the mass may be associated with some degree of mediastinal shift (Lopoo et al., 1999). It can be difficult to distinguish BPS from a CPAM, but when a systemic arterial supply is identified, the diagnosis of BPS is highly likely. If there is also an associated ipsilateral pleural effusion, the diagnosis is almost certainly BPS (Johnson and Hubbard, 2004). If the diagnosis is still in doubt, fetal MRI can be used to help distinguish between the two (Hubbard et al., 1999). Infradiaphragmatic masses also need to be distinguished from neuroblastoma, other tumors (such as lymphangioma), and adrenal hemorrhage (Curros and Brunelle, 2001; Winters and Effmann, 2001). As with CPAM, BPSs often regress spontaneously over time, and if there are no associated anomalies, the prognosis for the fetus is good (Adzick et al., 1998; Lopoo et al., 1999). Close ultrasound follow-up is prudent, however, until regression is documented. When pleural effusion occurs, there is a risk of development of tension hydrothorax. In these cases, repeated fetal thoracentesis or placement of a thoracoamniotic shunt can avert or resolve hydrops fetalis, which may improve the chances for survival (Lopoo et al., 1999).

On postnatal imaging, BPS may be present as a radiographic density on plain film. The presence of linear or cystic lucencies within the radiopaque density suggests a persistent communication between an extralobar sequestration and the GI tract (Leithiser et al., 1986; Laberge et al., 2005). An upper GI study can demonstrate communication with the GI tract and is indicated for surgical planning if feeding difficulties are present. Ultrasound can also be useful in demonstrating the lesion (most easily seen if it is located at the lung base), and Doppler studies can identify a systemic feeding vessel and venous drainage. The use of contrast-enhanced CT provides the best visualization of the parenchymal abnormalities but has variable sensitivity for delineation of the vascular supply, although the lesion itself can often be demonstrated even when it has resolved by fetal imaging (Fig. 49.9). Magnetic resonance with angiography can also be useful in demonstrating the lesion and its blood supply. Conventional angiography can identify the vasculature, but this has been replaced by the imaging modalities discussed above (Winters and Effmann, 2001).

Symptomatic BPSs are usually identified in the first 6 months of life, with respiratory distress or feeding difficulties. Less commonly, recurrent infection, congestive heart failure (because of a high output state), or pulmonary hemorrhage is present. Distress at birth can be severe, particularly with large lesions complicated by a pleural effusion or hydrops fetalis. For neonates that present with symptoms in the first week of life, early resection is indicated (Azizkhan and Crombleholme, 2008). Because the lesion is completely separate from lung, sequestrectomy is not a complex operation and can be done thoroscopically. However, the feeding vessels can be very large in more severe cases, mandating a thoracotomy. The primary risk associated with an unresected BPS is recurrent infection, although this risk is not well quantified, as

• **Fig. 49.9** Bronchopulmonary Sequestration. (A, B) Axial and coronal computed tomography images of an infant with a prenatally diagnosed chest mass (arrows). The mass is located at the left lung base, measuring $3.6 \times 3.0 \times 2.5$ cm. (C) The arterial supply is via a prominent collateral from the descending thoracic aorta at the level of the diaphragm (arrow). The venous drainage is via the azygos vein (not shown). These findings are consistent with an extralobar sequestration. The patient underwent thorascopic resection at 18 months of age. (Courtesy of Dr. Chirag V. Patel, Assistant Professor, University of California, Davis Health System, Department of Radiology, Sacramento, CA.)

there are probably adults with persistent, small, asymptomatic lesions. Consequently, as with CPAM, there is controversy as to whether fetal lesions that are not identified on plain film should be further investigated in asymptomatic infants and, in general, whether asymptomatic lesions should be resected. However, since sequestrectomy can now be accomplished thorascopically at 3 to 15 months, with rapid recovery and short hospitalization (Albanese et al., 2003), most lesions are surgically resected. In addition, this approach may preserve rib architecture and limit later chest wall deformity (Rothenberg and Pokorny, 1992). Early resection, before infectious complications (the primary risk associated with an unresected lesion) may limit complications, because secondary changes such as emphysema might be averted (Rosado-de-Christenson et al., 1993). Some have attempted coil embolization of the feeding vessel(s), with hope of complete or partial involution of the lesion (Curros et al., 2000; Chien et al., 2009). However, coil embolization may only result in partial vascular occlusion and incomplete regression, transient lower limb ischemia (because of

distal migration of embolic material), sepsis, and other blood vessel complications. Because of this, thorascopic resection is the current standard of care (Cho et al., 2012).

Other Cystic Lesions

Additional cystic lung lesions include congenital lobar emphysema, pleuropulmonary blastoma, and acquired cysts (pneumatocoeles or emphysema, in association with infection or BPD, respectively). Extrapulmonary cystic lesions include foregut cysts (bronchogenic or enteric duplication cysts) and neuroenteric cysts, which are less common than the other lesions and usually present later in infancy or childhood (Langston, 2003).

Congenital Lobar Emphysema

CLE occurs in 1 to 20,000 to 1 in 30,000 live births (Thakral et al., 2001). Because there is no evidence of lung destruction (true emphysematous changes), the common term CLE is a

misnomer, with this lesion, which is also known as *congenital lobar over inflation* (Langston, 2003). CLE is thought to arise from an obstructed lobar bronchus, which can either be intrinsic (including malacia) or extrinsic in origin. While the cause varies, the fundamental mechanism is that air can pass into the effected bronchus but is unable to leave, causing air trapping and lobar overexpansion. The upper lobes are most commonly affected, with the left upper lobe the single most commonly affected lobe. Lesions occupying multiple lobes are infrequent (Mani et al., 2004). Although the affected lobe is larger than usual, the number of alveoli in the involved area is within normal limits. The exception to this is the subset of these lesions with *polyalveolar lobe*, which was present in 9 of 33 cases of CLE in one series and has an overlapping clinical presentation with CLE (Mani et al., 2004). In polyalveolosis, the total number of alveolar is increased severalfold from normal, but the conducting airways are normal in size and number. This form of lung hyperplasia is consistent with pathophysiology associated with fetal airway obstruction (Langston, 2003).

CLE can be detected on fetal ultrasound, although it is difficult to make the correct diagnosis (Olutoye et al., 2000; Babu et al., 2001). Clinical reports have described the appearance of the lesion by ultrasound as cystic and/or echogenic, with mediastinal shift present, and subsequent regression with advancing gestation. As expected, these lesions are suspected to be CPAM or BPS, based on these findings. Fetal MRI can be helpful in characterizing the lesion, although it is not diagnostic (Olutoye et al., 2000). The postnatal clinical presentation and histology (after resection) distinguish CLE from the other lesions. The majority of children with CLE present with respiratory distress, cyanosis, or recurrent pulmonary infections in the first 6 months of life, with 13 of 33 (39%) symptomatic on the first day of life in one series (Mani et al., 2004). The severity of symptoms depends on the size of the affected lobe, the compression of the surrounding tissue, and the extent of mediastinal shift. Chest radiographs demonstrate a hyperinflated lung (transitioning from fluid filled to air filled over the initial postnatal days), with compression of other areas of the lung and mediastinal shift (Fig. 49.10). These findings are generally diagnostic. In children with less severe presentation, bronchoscopy or CT scan can be helpful in management decisions, because some surgeons will elect to manage these patients expectantly, with resolution of symptoms in some cases (Stigers et al., 1992). After resection, prognosis is generally good, with compensatory lung growth present on the affected side (McBride et al., 1980). Airway obstruction continues to be a feature of the disease on pulmonary function tests, although these findings could be consistent with either compensatory lung growth exceeding airway growth (dysanapsis) or intrinsic, diffuse airway abnormality.

Pleuropulmonary Blastoma

Pleuropulmonary blastoma (PPB) is a rare but malignant lesion arising from the lung or the pleura. Lesions can be predominantly cystic (type I), mixed cystic and solid (type II), or predominantly solid type (III) and can occur in association with other congenital lung lesions. The average age of diagnosis of type I, II, and III PPBs is 10 months, 34 months, and 44 months, respectively, and overall survival of type I PPBs is 80%–85%, while survival in type II and III patients is 45%–50% (Priest et al., 1996). The diagnosis and resection of this lesion are essential, because of the risk of metastasis, recurrence, and associated malignancies (Priest et al., 1996). Although these lesions tend to present later in childhood than CPAMs, there is overlap in the timing of presentation (Stocker, 2002), and PPB can be detected on fetal ultrasound (Miniati et al.,

2006); thus the consideration of this diagnosis in the perinatal period is relevant for counseling and surveillance, even if a newborn is not symptomatic.

Symptomatic infants usually present with respiratory distress. Before resection, most lesions are thought to be CPAMs, based on their appearance on fetal ultrasound or postnatal CT scan (Miniati et al., 2006). The treatment of choice for PPBs is surgical resection. While type II and type III lesions have been treated with adjuvant chemotherapy given their aggressive nature, there are increasing data to suggest adjuvant chemotherapy will reduce reoccurrence in type I patients as well (Miniati et al., 2006). Patients with type II and III lesions with residual disease following resection should also be treated with radiation therapy (Parsons et al., 2001). Resected lesions contain cuboidal or columnar epithelial cells with underlying rhabdomyosarcoma cells (or other sarcomas). The malignant cells may not be widespread in the lesion, making the diagnosis of PPB challenging even by histology (Stocker, 2002, 2009; Hill and Dehner, 2004). Because of the difficulty in distinguishing CPAMs from PPBs, careful histologic evaluation of prophylactically resected CPAMs is recommended, as those with stellate and spindle cells should be followed closely (Papagiannopoulos et al., 2001). Furthermore, PPBs may require a more extensive resection than CPAMs, so this distinction is important in determining surgical approach as well (MacSweeney et al., 2003). Tumor cells often have complex chromosomal rearrangements, and affected children can exhibit other neoplastic diseases: medullablastoma, nephroblastoma, thyroid dysplasia and malignancy, and brain sarcoma (Priest et al., 1996; Stocker, 2002). Kindreds also demonstrate multiple malignancies, suggesting that familial surveillance for disease might be indicated (Priest et al., 1996).

Postinfectious Pneumatocoles

Pneumatocoles are thin-walled, air-containing cystic structures resulting from alveolar and bronchiolar necrosis. In our experience, the most common infection associated with pneumatocoles in the newborn (maybe because of its higher frequency of infection) is *Staphylococcus aureus* pneumonia (Imamoglu et al., 2005). Other infections seen in the NICU that are associated with development of pneumatocole include pneumonia caused by *Actinomyces* and *Candida* species, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* (Stocker, 2009). Pneumatocoles are often present on initial chest radiograph documenting the infiltrate, although they can also occur later in the process. Given the thin wall, pneumatocoles can rupture, resulting in a pneumothorax that may be under tension or compress the lung tissue through mass effect, resulting in worsening respiratory status (Kunyoshi et al., 2006). Acutely, urgent interventions may be needed to improve ventilation and oxygenation in the setting of rupture. Placement of chest drains into the pneumatocole(s) in the absence of rupture, either percutaneously or under direct visualization via VATS, can be considered; however, the majority of these cysts are regressive and resolve spontaneously (Kunyoshi et al., 2006; Fujii and Moulton, 2008) (Fig. 49.11). For patients with chronic ventilator dependence, in particular former premature infants with BPD, resection of the affected lobe could be considered (Al-Saleh et al., 2008).

Hyperinflation and Emphysema in Chronic Lung Disease

Similar to postinfectious pneumatocoles, frank cysts or hyperinflated lung may develop in association with chronic lung disease of prematurity (BPD) or with certain developmental lung abnormalities. This cystic hyperinflation can cause compression of more functional areas of the lung, with consequent respiratory compromise

• **Fig. 49.10** Congenital Lobar Emphysema. (A) Chest radiograph showing significant hyperinflation of the right lung with mediastinal shift to the left. (B) Coronal chest computed tomography demonstrating hyperaeration of the right middle lobe consistent with congenital lobar emphysema right sided. (C) Intraoperative photo showing the right middle lobe characteristically “popping out” of the thoracotomy incision prior to resection. (D) Chest radiograph 3 days after right middle lobe resection showing normalization of lung volume on the right with resolution of mediastinal shift. (A, B, and D, Courtesy of Dr. Chirag V. Patel, Assistant Professor, University of California, Davis Health System, Department of Radiology, Sacramento, CA. C, Courtesy of Dr. Clifford C. Marr, Clinical Professor, Sutter Medical Group, Department of Surgery, Division of Pediatric Surgery, Sutter Medical Center, Sacramento, CA.)

(Moylan and Shannon, 1979; Stocker, 2009). While this very severe chronic lung disease complication of prematurity rarely occurs today, affected infants can acutely decompensate or remain ventilator dependent despite maximal medical therapy. Evaluation of 6 infants with BPD and decompensated lobar hyperinflation in one series revealed extensive lobar bronchomalacia, with almost complete collapse of the affected airway through the expiratory phase or the entire respiratory cycle (Azizkhan et al., 1992). Lobectomy results in acute improvement, although ultimately only half of infants who are so treated survive.

Miscellaneous Cysts

Lymphatic, lymphangiomatous, mesothelial, and parenchymal cysts can be detected in the thorax, so these lesions may need to be included in the differential diagnosis of cystic lesions (Langston, 2003).

Disorders of the Diaphragm

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) is a disorder of lung and pulmonary vascular hypoplasia that results from failure of formation of the diaphragm (Areechon and Eid, 1963; Kitagawa et al., 1971; Hislop and Reid, 1973). This may be due to primary deficiency of the embryonic pleuroperitoneal fold, which is one of the critical primordial diaphragmatic structures that must fuse at 6 to 8 weeks' gestation to form an intact diaphragm (Clugston et al., 2006). Failure of this event results in herniation of abdominal contents into the hemithorax, and the subsequent arrest of precapillary airway branching at 10 to 14 weeks' gestation is consistent with this early developmental defect. Hypoplasia is bilateral, although the lung ipsilateral to the hernia is most affected. Airway diameter is

• **Fig. 49.11** Postinfectious Pneumatocoeles. Chest radiographs from a former preterm infant with pneumatoceles secondary to *Staphylococcus aureus* pneumonia. Cysts are compressing the lung and causing mediastinal shift (left). Placement of draining thoracostomy tubes decompressed the cysts and decreased mediastinal shift, but the infant ultimately succumbed to respiratory failure secondary to bronchopulmonary dysplasia.

substantially decreased, but increase in airway muscle occurs as a later postnatal event (Broughton et al., 1998). Although acinar alveolar counts are normal, overall alveolar hypoplasia is present due to the branching defect ($<10 \times 10^6$ vs 50×10^6 alveoli at term).

Because of the interdependence of lung and vascular growth, both alveolar and capillary surface areas are decreased (Hislop and Reid, 1973; Kitagawa et al., 1971; Joshi and Kotecha, 2007). Vascular branching is impaired, with a decreased diameter of the vessels and increased muscle mass that is inversely related to the degree of lung hypoplasia (Kitagawa et al., 1971; Naeye et al., 1976). Some morphometric reports have demonstrated abnormal distal extension of the muscular media to the intra-acinar arteries, whereas others have not demonstrated abnormal distal muscularization (Kitagawa et al., 1971; Geggel et al., 1985). The mechanism of developmental lung and vascular hypoplasia is unknown but may include decreased static transthoracic pressure (secondary to open communication with the peritoneal cavity) and decreased phasic pressure alterations (secondary to impaired fetal breathing movements). Compensatory alveolar growth does occur in survivors, although it is more pronounced in the contralateral lung, and relative perfusion to the ipsilateral lung can be persistently diminished (Wohl et al., 1977; Thurlbeck et al., 1979; Okuyama et al., 2006). These findings are consistent with evidence of greater injury present in the more hypoplastic and vulnerable ipsilateral lung, compared with the contralateral lung in survivors of CDH, with consequent impairment of lung growth (Hislop and Reid, 1973; Wohl et al., 1977; Thurlbeck et al., 1979).

Ninety-five percent of CDHs are posterolateral (Bochdalek) hernias (Deprest et al., 2014). The remaining 5% are either anterior, retrosternal, or peristernal (Morgagni). CDH is more common on the left side (75%–80% of cases) than the right, probably because of slightly later fusion of the left-sided structures. Bilateral hernias account for 1%–2% of cases. Morgagni hernias are much less frequent in occurrence and usually are not associated with substantial lung hypoplasia, although they may be associated with

pericardial, sternal, and abdominal wall defects as part of the pentalogy of Cantrell spectrum. There is a predominance of males to females in CDH (1.4 to 1.6:1 ratio), and the occurrence of CDH (including stillbirths) is about 1 in 4000 births (Levison et al., 2006; Yang et al., 2006; Gallot et al., 2007). Additional anomalies occur in about 40% of affected infants and fetuses (Yang et al., 2006; Gallot et al., 2007). Musculoskeletal (including ribs, vertebrae, and digits) and cardiac anomalies are most common, although the patterns of malformation differ in association with right-sided CDH compared to left-sided CDH (Slavotinek et al., 2007). CDH can be associated with aneuploidy (most frequently trisomy 18), and it can present in autosomal recessive (e.g., Fryns syndrome), sex-linked (e.g., Simpson–Golabi–Behmel syndrome), and autosomal dominant (e.g., Cornelia de Lange syndrome) disorders (Slavotinek, 2007; Slavotinek et al., 2007). With the exception of these disorders, recurrence rate is quoted at 1%–2%, and more recent genetic studies have identified micro-deletions in affected infants through use of microarray technology (Slavotinek, 2005; Kantarci et al., 2006). It is unclear whether or not infants with isolated CDH (no other anomalies found by prenatal and postnatal investigation) are at increased risk for these minor chromosomal aberrations, because large-scale investigations have taken place with very limited positive findings. Single gene mutations have been identified in animal models and some humans as causal in CDH, and certain areas of the genome may be critical regions, wherein other causal genes might be found (Clugston et al., 2006; Ackerman and Pober, 2007).

In recent population-based studies, overall survival among liveborn affected infants ranged from 57% to 73% (Collin et al., 2016; Partridge et al., 2016). This is slightly improved from a 52% to 61% survival rate just a decade ago (Stege et al., 2003; Colvin et al., 2005; Yang et al., 2006; Gallot et al., 2007). Those patients with left-sided diaphragmatic hernias fare better than those with right-sided hernias, with survival rates being 73%–69%, respectively; however, this difference is not statistically significant. While the survival rate is similar, those patients with right-sided

CDH have higher rates of pulmonary morbidity, including an increased need for tracheostomy, long-term vasodilatory therapy, and greater likelihood of requiring supplemental oxygen at the time of hospital discharge (Partridge et al., 2016). Survival of liveborn infants with isolated (no additional anomalies) CDH has been higher (63%–77%) than survival in liveborn infants with other anomalies or chromosomal aberrations (19%–43%) (Stege et al., 2003; Yang et al., 2006; Gallot et al., 2007). Survival is low (<10%) in affected infants with chromosomal abnormalities, and there is a risk of intrauterine fetal demise in both isolated (2%) and nonisolated (11%) CDH. Although individual referral centers have reported survival rates ranging from 75% to 93% (Bohn, 2002; Boloker et al., 2002; Downard and Wilson, 2003), there have been studies documenting a hidden mortality, demonstrating that a proportion of liveborn neonates die within hours of birth and before arrival at a surgical center (Harrison et al., 1994; Mah et al., 2009). In a recent study from Ontario, Canada, survival decreased from 67% to 58% for multicenter compared to population-based data, after accounting for infants who never reached a referral center (Mah et al., 2009).

Both population-based and center-based studies have identified some risk factors for mortality for liveborn infants undergoing full resuscitative measures and ongoing neonatal care. All of these are probably related to the severity of the CDH, with respect to the degree of lung and vascular hypoplasia. For instance, prenatal diagnosis has been associated with increased mortality and may be due to the identification of more severe CDH (because mediastinal shift will be more pronounced and present earlier in gestation; see later discussion) (Stege et al., 2003; Colvin et al., 2005; Gallot et al., 2007; Stevens et al., 2009). A recent multicenter, retrospective Children's Hospital Neonatal Database analysis of 677 children with CDH identified six variables independently associated with mortality and hospital length of stay greater than 109 days: infants that were small for gestational age, those with major birth anomalies, 5-minute Apgar scores less than or equal to three 3, acidosis at the time of referral, those requiring ECMO, and those with bacteremia (Murthy et al., 2016). Other postnatal factors that are associated with increased mortality include prematurity (<37 weeks) and air leak, conditions associated with immature lung development, and/or increased risk for lung injury (Levison et al., 2006; Tsao et al., 2010).

Interestingly, two studies have shown somewhat conflicting data regarding the timing of term delivery and survival. For infants receiving ECMO support, late-term (40–41 weeks' gestation) infants had somewhat better survival compared with early-term (38–39 weeks' gestation) infants, although the relationship was not statistically significant, and fewer ECMO-related complications were seen in the late-term group (Stevens et al., 2002). However, overall survival was slightly better for early-term (37–38 weeks' gestation) versus late-term (39–41 weeks' gestation) infants in another study that included infants not receiving ECMO support (Stevens et al., 2009). Other data show that infants not born at a tertiary center (outborn), but subsequently transferred to a tertiary center, have higher survival rates than those that are born at a tertiary center (inborn), which may reflect the hidden mortality associated with more severe, prenatally diagnosed CDH (Boloker et al., 2002; Levison et al., 2006). For those infants who do undergo surgical repair, the need for a prosthetic patch is associated with subsequent mortality, indicating a larger diaphragmatic defect and probably more severe lung hypoplasia (Wilson et al., 1997; Lally et al., 2006; Bryner et al., 2009).

Prenatal Diagnosis and Management

CDH is usually suspected on prenatal ultrasound when mediastinal shift away from the side of the hernia is appreciated. Prenatal detection rates are higher with left-sided than right-sided hernias, and bilateral hernias can be difficult to discern because of the distorted anatomy. CDH in fetuses with additional anomalies are also detected at a higher rate than CDH in isolated cases (Gallot et al., 2007). Fetal MRI can be helpful in determining the diagnosis, if the anatomy is difficult to identify. A prenatal diagnosis of CDH mandates careful evaluation for other anomalies, including a fetal echocardiogram, because of the high rate of additional anomalies and their association with lower survival rates. Some of this evaluation may be limited by the anatomic distortion caused by the hernia. A karyotype and other genetic analysis (as indicated) are also recommended. Additional prognostic information regarding the severity of the hernia can be gathered during prenatal evaluation by ultrasound and MRI, although the prognostic ability of these measures is likely center dependent, as survival varies to some extent across centers. The most useful discriminator of CDH severity is herniation of the liver into the hemithorax (Metkus et al., 1996; Jani et al., 2006). Liver herniation can occur with both right-sided and left-sided CDH. In left CDH, the left lobe of the liver herniates in the thorax; thus the course of the hepatic vasculature is distorted and indicative of liver herniation. Herniation of the liver is also predictive, with one study showing a significantly higher survival rate in fetuses without liver herniation (74%) versus those with herniation (45%) (Mullasery et al., 2010). Further research looking at the predictive nature of prenatal ultrasound in the assessment of liver herniation has demonstrated that sonographic measurements (liver-to-thorax ratio and stomach position) are predictive of survival outcomes in those with isolated left-sided CDH (Werneck Britto et al., 2015; Sananes et al., 2016). The prenatal liver-to-thorax ratio can also be predictive of the need for ECMO.

Other prenatal discriminators of severity that have been used include stomach herniation and polyhydramnios (a later finding, secondary to GI obstruction or esophageal dysmotility). A number of ultrasound measures have been developed as intrauterine measures of lung size (Keller, 2007). The lung-to-head ratio (LHR) is widely used for this purpose (Metkus et al., 1996). It is the perpendicular area of the lung contralateral to the hernia at the level of the cardiac atria divided by the biparietal diameter. It has been used predominantly in mid-gestation (22–27 weeks' gestation), with an LHR ≤ 1.0 combined with liver herniation accepted as the most severe group of CDH. LHR has been studied in left CDH, although it has also been extrapolated to right CDH and probably has prognostic ability; LHR thresholds for severity could be lower in right CDH, since the normal right lung is larger than the left lung (Hedrick et al., 2004; Peralta et al., 2005). Investigators have developed nomograms for normal LHR over 12 to 32 weeks, which has led to an observed-to-expected (O/E) LHR measurement, employing the mean LHR at any gestational age as the "expected LHR," which increases with advancing gestational age because of a more rapid increase in lung area compared with head circumference (Peralta et al., 2005). It follows that the LHR ≤ 1.0 will represent a higher O/E LHR earlier in gestation than it does later in gestation, and the O/E LHR will be higher with right CDH than left CDH for a given LHR and gestational age (Jani et al., 2009a). In a large database of 354 fetuses with isolated CDH (including 25 fetuses with right CDH), the O/E LHR was predictive of survival, independent of liver herniation (Jani et al., 2007). Subsequent analyses of this data have stratified fetuses with and without liver herniation, because survival does differ between these groups for

a given O/E LHR range (Deprest et al., 2009). In these analyses, survival was less than 20% for fetuses with isolated left CDH and O/E LHR less than or equal to 25%. Fetuses with a higher O/E LHR of 26%–35% survived in greater numbers: 30% if liver was herniated and almost 60% if liver was not herniated. The lower bound of the 95% confidence interval (CI) for O/E LHR in unaffected fetuses is 60% (Jani et al., 2007). Decreasing O/E LHR was also related to increasing time on assisted ventilation, prolonged hospitalization, and an increased risk for prosthetic patch repair (Jani et al., 2009a).

Fetal MRI techniques have also been pursued for prognostic information in CDH. Liver herniation can be determined by fetal MRI, and at some centers it is the preferred technique for this determination. A number of different nomograms to determine lung volume as a percent of normal (based on estimated fetal size or gestational age) have been developed. Recently, Büsing et al. (2008) evaluated seven published nomograms for estimation of relative fetal lung volume in 68 fetuses with isolated left CDH evaluated at their center. They generated receiver operating characteristic curves for each of the seven equations and found high (0.800–0.900) area under the curve (AUC) for prediction of survival, regardless of technique used. In this dataset, prediction of need for ECMO was not as strong (AUC 0.653–0.739), although individual centers have found that relative fetal lung volume is a very useful predictor of the need for subsequent ECMO support (Barnewolt et al., 2007).

Early attempts at fetal intervention for CDH focused on an anatomic repair of the diaphragmatic defect; however, this approach was quickly abandoned after survival outcomes did not improve (Harrison et al., 1997). Fetal intervention has since shifted its focus to enhancing intrauterine lung growth via endoscopic temporary balloon tracheal occlusion. Only fetuses likely to be the most severely affected newborns are candidates, if additional anomalies are not found after careful investigation. A randomized controlled trial evaluating this technique was terminated prematurely because of unexpectedly high survival in the control group, with no difference in survival between tracheal occlusion and standard care infants (Harrison et al., 2003). The tracheal occlusion procedure was complicated by premature delivery (mean gestational age 30.8 weeks), often stemming from premature rupture of the membranes, and this may have compromised survival in the intervention group. With development of smaller instruments, this technique can now be accomplished as a fully endoscopic procedure, and the incorporation of a second procedure to remove the tracheal balloon (i.e., plug–unplug) has also decreased the need for delivery by EXIT procedure, allowing for vaginal delivery in the majority of cases (Jani et al., 2009b). The European Fetal Endoluminal Tracheal Occlusion (FETO) task group has been performing minimally invasive tracheal occlusion in fetuses with LHR less than or equal to 1.0 with promising results demonstrating an improved survival to discharge and a later mean gestational age at the time of delivery (33.5 weeks) (Jani et al., 2005). This was attributed to the less invasive nature of the procedure. With operator experience, the procedure has been accomplished more rapidly, and shorter procedures were associated with lower rates of premature membrane rupture. Elective prenatal removal of the intratracheal balloon (i.e., unplug) was accomplished at a median of 34 weeks in 70% of the cases. Survival to neonatal discharge was 47% (98 of 210); 6 deaths were fetal and 10 deaths occurred secondary to difficulty with removal of the intratracheal balloon. From their historical experience, the investigators cite an expected survival of only 24%. In a subset of these fetuses, and some expectantly managed with CDH, Cannie

et al. (2009) evaluated changes in relative lung volume over gestation by fetal MRI. They found that relative lung volume was largely unchanged in fetuses without intervention, and it tended to increase more consistently in fetuses with CDH when tracheal occlusion was undertaken at greater than or equal to 29 weeks' gestation ($n = 8$). Most recently, a small randomized controlled trial comparing FETO to standard postnatal management found that 50% of fetuses treated with tracheal occlusion survived to 6 months of life compared with 4.8% in the postnatal treatment group (Ruano et al., 2012).

Postnatal Diagnosis and Management

Most newborns with CDH will present immediately or within several hours of birth with respiratory distress, cyanosis, decreased breath sounds on the hernia side, and a scaphoid abdomen. An occasional infant will not have symptoms until several days or months of age and often will have feeding intolerance and mild respiratory distress (Kitano et al., 2005). An initial chest radiograph will show a smaller lung on the hernia side, with bowel gas in the chest and shift of mediastinal structures (Figs. 49.12–49.13). The findings of a small lung, with no mediastinal shift and usually without concern for herniated bowel, should raise suspicion for other diagnoses, which may require an alternate surgical approach or may not require surgery at all (see later discussion). Newborns with a fetal diagnosis of CDH or those presenting soon after birth are usually mechanically ventilated with an endotracheal tube, and a Replogle (Covidien - Medtronic, Minneapolis MN) is placed for continuous gastric suction to minimize accumulation of thoracic intraintestinal air and reduce lung compression.

Hypoplastic lungs with small alveoli have poor compliance, and thus ventilation is severely reduced (Keller, 2007). Combined with the restrictive pulmonary vascular bed and consequent pulmonary hypertension, this leads to severely impaired oxygenation. Because these physiologic challenges cannot be overcome without lung growth, most high-volume centers use a gentle ventilation strategy. This strategy attempts to achieve adequate oxygen delivery and preserve the potential for lung growth while minimizing oxygen toxicity and ventilator-induced lung injury (barotrauma). Actual targets for ventilation and oxygenation vary somewhat, but consistency in care within a center is important (Logan et al., 2007). The ventilation target is often an arterial partial pressure of carbon dioxide (PCO₂) of 50–65 mm Hg (permissive hypercapnia). For oxygenation, a more liberal strategy allows for a preductal (right upper extremity) and postductal (descending aorta or lower extremity) arterial saturation (SaO₂) differential, with oxygenation targets based on preductal SaO₂ (permissive oxygenation). Oxygenation targets are generally preductal SaO₂ greater than or equal to 95% in less severely affected infants and SaO₂ greater than or equal to 85% in more severely affected infants. Ventilator pressures are limited, with either positive inspiratory pressure (PIP) targeted at less than or equal to 25–28 cm H₂O or mean airway pressure on high-frequency ventilation at less than or equal to 15 cm H₂O. Aggressive weaning strategies are used to achieve gentle ventilation goals and to minimize lung injury. Lung recruitment is not an effective strategy to achieve persistent improvements in oxygenation in CDH (Kinsella et al., 1997), and increases in PIP to achieve transient improvements in oxygenation lead to further increases in ventilator support, with worsening compliance because of lung injury and edema (Kays et al., 1999). There are also some centers that advocate low PEEP and high ventilator rates (which are physiologic in lung hypoplasia). With high ventilator rates, gas trapping and auto-PEEP may be an important factor, so limitation of the PEEP set on the ventilator is important (Boloker et al.,

• **Fig. 49.12** Left Congenital Diaphragmatic Hernia. (A) Radiograph of an infant with congenital diaphragmatic hernia (CDH) without liver or stomach herniated into thorax. He subsequently underwent primary repair of the diaphragmatic defect, was extubated within several days of surgery, and was discharged to home without supplemental oxygen. (B) Radiograph of an infant with severe CDH with liver and stomach herniated into thorax. He subsequently required extracorporeal membrane oxygenation (ECMO) support, underwent prosthetic patch repair for diaphragmatic aplasia, and succumbed to respiratory failure and pulmonary hypertension after decannulation from ECMO support.

2002). In addition, low PEEP (2–3 cm H₂O) is associated with higher lung compliance in infants with CDH than PEEP of 4–6 cm H₂O (Dinger et al., 2000).

Employment of gentle ventilation strategies has been associated with improved survival at individual centers (Wilson et al., 1997; Kays et al., 1999); however, regardless of actual targets for ventilation and oxygenation and preferential mode of ventilation, it is likely that other aspects of care, such as infant stimulation and positioning and sedation and feeding practices, affect survival and other outcomes. Although there are a number of ancillary treatments employed in infants with CDH (prenatal glucocorticoids, surfactant replacement therapy, inhaled nitric oxide, and other pulmonary vasodilator therapies), there are no studies documenting broad efficacy of these treatments in term infants with CDH. Some have advocated the primary use of high-frequency ventilation in these infants, but there is no evidence of benefit to survival or other outcomes based on the mechanical ventilation technique alone (when similar permissive targets are used) (Snoek et al., 2016). In addition, the use of prostaglandin infusion to maintain ductal patency and improve right heart function in cases of prolonged pulmonary hypertension has been advocated (Bohn, 2002). The one ancillary treatment that has shown benefit is the use of ECMO, which improved survival to hospital discharge in the United Kingdom Collaborative study, although the effect dissipated at follow-up with later deaths among initial survivors (Mugford et al., 2008).

ECMO can be used to rescue newborns with CDH, particularly those with lung injury evident by pneumothorax (Sebald et al., 2004), and it may be used in the setting of gentle ventilation (where pneumothorax is a less frequent occurrence), to avoid prolonged high ventilator pressures or fraction of inspired oxygen (FiO₂). Although CDH has become the most common indication for neonatal ECMO (other than cardiac defects), its efficacy is difficult to assess given the absence of clinical trials. However,

those with CDH who go onto ECMO have a 40%–50% survival rate based on observational data (Rais-Bahrami and Van Meurs, 2005; Seetharamaiah et al., 2009). Because ECMO is a temporary therapy designed to allow for resolution of a reversible process, it is unlikely that all infants with CDH will benefit from ECMO support; some will have lethal pulmonary hypoplasia (Antunes et al., 1995). Thibeault and Haney described persistent pulmonary hypertensive changes in vessels of infants with CDH dying after ECMO support, and others have described recurrent pulmonary hypertension (Payne et al., 1991; Thibeault and Haney, 1998). The results of ECMO in CDH greatly depend on patient selection criteria, which varies widely among institutions. The primary indication for ECMO should be failure of conventional therapy. This failure can be characterized by persistent productal SaO₂ less than or equal to low 80s, hypotension resistant to fluid/inotropic support, peak inspiratory pressures less than 30 cm H₂O, or worsening metabolic acidosis (Downard and Wilson, 2003). For those who do go on ECMO, a duration of ECMO support greater than 2 weeks and the use of renal replacement therapy for renal insufficiency have been identified as independent predictors of mortality. Survival among both of these groups was approximately 20% (2 of 11 for prolonged ECMO and 4 of 18 for renal insufficiency) (Tiruvoipati et al., 2007). Longer ECMO runs, renal complications, and multiple complications were also independently associated with mortality in infants with CDH in an analysis from the Extracorporeal Life Support Organization database (Stevens et al., 2002). Thus failure to decannulate an infant at less than 10 to 14 days of support is probably an indicator of severe lung and vascular hypoplasia. In these severely affected infants, it often takes longer than 4 weeks to resolve pulmonary hypertension (Dillon et al., 2004; Keller et al., 2006), and therefore awaiting resolution of pulmonary hypertension in these cases before decannulation would require prolonged ECMO support. Prolonged ECMO runs are prone to mechanical complications, which may further prolong

• **Fig. 49.13** Congenital Diaphragmatic Hernia and Hepatopulmonary Fusion. Chest radiographs in two infants with respiratory distress at admission to the intensive care nursery and at 3 and 5 years of age (left to right). *Upper panel* shows infant with right congenital diaphragmatic hernia with liver herniated into thorax and diaphragmatic aplasia. Note mediastinal shift into left hemithorax, with subsequent improvement in aeration and then normalization of right lung volume. *Lower panel* shows infant with hepatopulmonary fusion. Surgical repair required resection of hypoplastic nubbin of lung. Note lack of mediastinal shift at presentation, compensatory growth of left lung with trachea deviated to the right, and scoliosis.

the ECMO run or be irrecoverable. Thus it is unclear to what degree prolonging ECMO support could increase survival in CDH, unless there is still evidence of reversibility in the infant's condition. In the case of availability of a specific therapy, such as perfluoro-carbon partial liquid ventilation, wherein lung growth might be induced, the benefits of continuing ECMO support might become evident (Hirschl et al., 2003). This therapy, however, is still controversial, with recent clinical studies showing that perfluoro-carbon ventilation does not improve pulmonary vascular remodeling and CDH-associated pulmonary hypertension (Shah et al., 2016). Otherwise, strategies to limit the duration of ECMO support in CDH could be employed, accepting ventilator settings at decannulation that are significantly higher than what might otherwise be acceptable for newborns coming off ECMO support. These strategies could include prevention of complete lung collapse with aggressive pulmonary toilet, because re-recruitment of lung volume can be difficult in these infants (which may be related to small-caliber airways that have been damaged by pre-ECMO support regimens). Also, for infants cannulated prerepair, performance of the CDH repair post-ECMO decannulation could further limit time on ECMO support. Surgical repair of the diaphragmatic defect while on ECMO is associated with higher mortality, even after adjusting

for other markers of CDH severity (Bryner et al., 2009). This phenomenon may be related to hematologic complications from the repair (which are independently associated with decreased survival) (Stevens et al., 2002). However, some centers advocate CDH repair as soon as possible after stabilization on ECMO support (Bryner et al., 2009). In addition, some centers utilize an "EXIT-to-ECMO" approach for fetuses with high-risk criteria based on fetal evaluation (low relative lung volume) (Kunisaki et al., 2007b). These fetuses are intubated and ventilated during an EXIT procedure. If they meet certain criteria for adequate gas exchange, they are delivered for conventional management. If they do not meet these criteria, they are cannulated and placed on ECMO support. Using this strategy, (Kunisaki et al., 2007b) reported a 71% (10 of 14) survival with 11 infants going directly to ECMO support and 7 of 11 surviving. Most infants required prolonged mechanical ventilation and hospitalization.

Repair of the diaphragmatic defect usually occurs after some degree of stabilization of cardiopulmonary status, either with conventional therapy or ECMO support. Nakayama et al. (1991) demonstrated that lung compliance improves before surgery after a short period (several days) of stabilization in infants with CDH, and Sakai et al. (1987) demonstrated that compliance worsens

with early surgery in almost all infants. Keller et al. (2004) studied infants with severe CDH (liver herniation and LHR <1.4) and found that, although compliance did not improve before surgery after a period of stabilization, compliance did improve within 24 hours after surgery. In low-risk infants that do not require ECMO, the Congenital Diaphragmatic Hernia Study Group found that the timing of surgery did not seem to affect survival and that those who underwent surgery at age 0–3 days, 4–7 days, or greater than 8 days had similar mortality rates when adjusted for known risk factors (Hollinger et al., 2014). Thus the rationale for delayed surgery is sound with respect to lung function, but specific clinical parameters to guide the timing of elective CDH repair remain unknown. Some centers advocate very delayed surgery, while awaiting complete resolution of pulmonary hypertension (Wung et al., 1995). However, this approach can be problematic, because pulmonary hypertension may require weeks for resolution (Dillon et al., 2004; Keller et al., 2010). Subsequent failure to reduce the hernia contents is likely to delay establishment of enteral nutrition, with a consequent increased risk of infection and complications from parenteral nutrition. The achievement of even modest reduction in FiO_2 before surgery allows for a transient increase, if needed, after surgery, and even in cases where FiO_2 remains high, the modest improvement in lung function that occurs with surgery may help with further recovery for the infant in the most severe cases. Another issue with respect to timing of surgery arises when an infant also has congenital heart disease that requires neonatal surgery. Most centers will undertake CDH repair and then proceed to the cardiac surgery once the infant meets reasonable hemodynamic criteria for that surgical intervention (Cohen et al., 2002). In newborns who might require urgent cardiac surgery, survival is unlikely unless the lung hypoplasia and pulmonary hypertension are very mild. In a large series of 280 infants with CDH and congenital heart disease, overall survival was 41% but only 5% for infants with single ventricle physiology and 18% (2 of 11) for infants with total anomalous pulmonary venous return (Graziano, 2005).

Surgical repair of CDH involves reduction of the hernia contents and closure of the diaphragmatic defect. The surgical approach traditionally has been via laparotomy (subcostal incision on the side of the hernia), to abrogate the detrimental effect of thoracotomy on lung function. However, some surgeons will preferentially do a thoracotomy for a right CDH repair. With the advance in endoscopic technology, thoracoscopic and laparoscopic repairs are being performed in selected patients (Zani et al., 2014). These patients include infants who have achieved low ventilator settings and FiO_2 before surgery. Despite both thoracoscopic and laparoscopic repairs being feasible, there are questions about the safety and efficacy of these approaches, with minimally invasive techniques being linked to higher rates of reoccurrence, as well as intraoperative acidosis and hypercapnia, particularly with thoracoscopic repair (Kim et al., 2009; Tsao et al., 2011; Bishay et al., 2013). Additional randomized controlled trials are needed to determine the efficacy of minimally invasive repairs and to define the specific patient populations who are most appropriate for a minimally invasive repair.

Regardless of the surgical approach, when the diaphragmatic defect cannot be closed primarily, a prosthetic patch is used to bridge the gap. There is significant variability among surgeons in the need for patch repair, however. Clinical series have demonstrated that it is more common in the case of liver herniation and right CDH (which may also be an association with herniated liver) (Fisher et al., 2008; Kunisaki et al., 2008). Patch repair can be accomplished with use of a polytetrafluoroethylene (PTFE/Gore-Tex, W.L. Gore & Associates, Inc., Flagstaff, AZ)

or a bioabsorbable intestinal mucosa (SurgiSIS, Cook Medical Inc., Bloomington, IN) material. Polypropylene (Marlex, Bard Davol, Warwick, RI) and other materials have been used sporadically (Riehle et al., 2007). Use of an abdominal silo and/or prosthesis to close the abdominal wall is sometimes necessary and may decrease the need for a prosthetic diaphragm (Rana et al., 2008; Bryner et al., 2009). Temporary abdominal closures with skin or vacuum-assisted closures have also been used, most commonly in children who are repaired while on ECMO (Laje et al., 2016). Some surgeons advocate construction of a latissimus dorsi flap for initial CDH repair when primary closure of the diaphragmatic defect cannot be accomplished (Barbosa et al., 2008). This technique allows for some potential for diaphragmatic function in the innervated flap, which usually remains abnormal at late follow-up even with primary repair (Arena et al., 2005). However, the technique is time consuming and may not be tolerated in patients during the acute neonatal period, so others have reserved this technique only for hernia recurrence (Sydorak et al., 2003). Generally, use of a prosthetic patch for diaphragmatic closure is associated with increased risk of hernia recurrence, although the actual risk varies widely and may be dependent on multiple factors, including surgical technique and the type of patch used (Jancelewicz et al., 2010). Recurrent herniation may be associated with small bowel obstruction. It is also associated with persistent chest wall deformity, which might be due to the severity of the underlying disease or the complication of re-herniation (requiring multiple surgical procedures). Some surgeons have moved toward use of composite patches (more than one material), which may decrease the risk of recurrence by allowing for both durability and accommodation of rapid growth in infancy (Riehle et al., 2007; Jancelewicz et al., 2010).

Another area of variable practice is related to the intraoperative placement of a thoracostomy tube. Some of this controversy is related to the application of negative pressure, because that creates additional transpulmonary pressure and potential for barotrauma and lowers lung compliance (Dinger et al., 2000). However, negative pressure drainage is not necessary. Because the ipsilateral thorax will fill with fluid after reduction of the hernia contents as a result of the hypoplastic lung, placement of an anterior thoracostomy tube in a supine infant will prevent the accumulation of excess pleural fluid (which can occur with chylothorax). Chylous pleural effusion will cause respiratory compromise. However, it may be difficult to ascertain the cause of this deterioration because mediastinal structures remain shifted for some period of time postoperatively and may be modestly more exaggerated with tension hydrothorax. Chylothorax is not uncommon after CDH repair. In a recent series, it occurred in 7% of infants (10 of 152), and it was more common in infants who required prosthetic patch repair (8 of 10) (Gonzalez et al., 2009). Both surgical trauma and underlying hemodynamics due to right heart failure may contribute to the cause of this problem in infants with CDH (see Chylothorax earlier, for diagnosis and management).

Long-Term Morbidity

Survivors of CDH have substantial pulmonary and GI morbidity at follow-up (Muratore et al., 2001a, 2001b). Early gastroesophageal reflux following repair occurs in up to 40% of CDH patients and is more common in patients who undergo patch closure or have an intrathoracic stomach (Peetsold et al., 2010). In addition, failure to thrive is common with many patients requiring supplemental enteral feedings via gastrostomy tube. Although low lung volumes and restrictive lung disease may be seen in the first months of life, obstructive lung disease is the most common finding in early childhood and at later follow-up (Vanamo et al., 1996; Koumbourlis

et al., 2006). Children requiring prosthetic patch repair and prolonged mechanical ventilation are most likely to have later morbidity, but the relative contribution of anatomic abnormalities, physiologic derangements, and secondary injury to these outcomes is unknown. Developmental delay and hearing loss also occur and require careful follow-up for early identification and intervention (Jaillard et al., 2003; Cortes et al., 2005; Friedman et al., 2008; Keller et al., 2008).

Hepatopulmonary Fusion

Hepatopulmonary fusion probably represents a severe form of CDH. It has been described variably in the literature as both CDH and severe eventration (Rais-Bahrami et al., 1996; Keller et al., 2003; Robertson et al., 2006). All reported cases have occurred on the right side, although there is a report of a late-presenting left CDH with fusion of liver and lung tissue (Baeza-Herrera et al., 2000). It is not clear if this is the same entity that other authors have described, because these infants usually present in extremis, with respiratory failure and pulmonary hypertension (Rais-Bahrami et al., 1996; Keller et al., 2003; Robertson et al., 2006).

The embryology of this defect is speculative, and the distinction between severe CDH versus eventration is probably not critical. However, the diaphragm is not intact, it is usually moderately to severely hypoplastic, and there is fusion of hepatic and pulmonary tissue without pleura or liver capsule present, no dissectable plane, and a fibrous membrane adherent to the liver and the lung (Slovic et al., 2000). In cases where hepatopulmonary fusion is determined or suspected, there is a lack of mediastinal shift, consistent with severe right lung hypoplasia rather than a mass effect from a large right CDH with herniated liver (Slovic et al., 2000; Keller et al., 2003).

The suspicion of this diagnosis is important, because the surgical approach may differ. The need to separate the liver and the lung (usually requiring ligation or resection of part of the hypoplastic lung because of the risk of air leak and hemorrhage) will require a thoracotomy. MRI has been utilized preoperatively to help make this distinction and found enhanced lung tissue adherent and conforming to the dome of the liver in a case of hepatopulmonary fusion, suggestive of the anatomy subsequently encountered at the time of surgical repair (Keller et al., 2003). The goal of surgery is to separate the thoracic and abdominal cavities, often requiring placement of a prosthetic patch. If these children survive, later growth of the right lung is much more restricted than it is in children with severe right CDH (see Fig. 49.13). Whether this is due to more pronounced ipsilateral lung hypoplasia, less pronounced contralateral lung hypoplasia, or the need for resection at the time of surgical repair is unclear. However, chest wall deformity and scoliosis are significant problems in these children.

Congenital Eventration of the Diaphragm

Congenital eventration of the diaphragm occurs when the hemidiaphragm is partially or completely replaced by fibroelastic tissue, leading to a thinned, pliable portion of the diaphragm. Unlike CDH, the diaphragm is intact with normal insertion points. However it is elevated, and thus intra-abdominal organs are present in the thorax but still confined below the diaphragm. It can be difficult to distinguish eventration from a diaphragmatic hernia with a sac. The right and left hemidiaphragms are equally affected, and 13% (6 of 48) of affected infants had bilateral eventration in an early series (Wayne et al., 1974; Tsugawa et al., 1997).

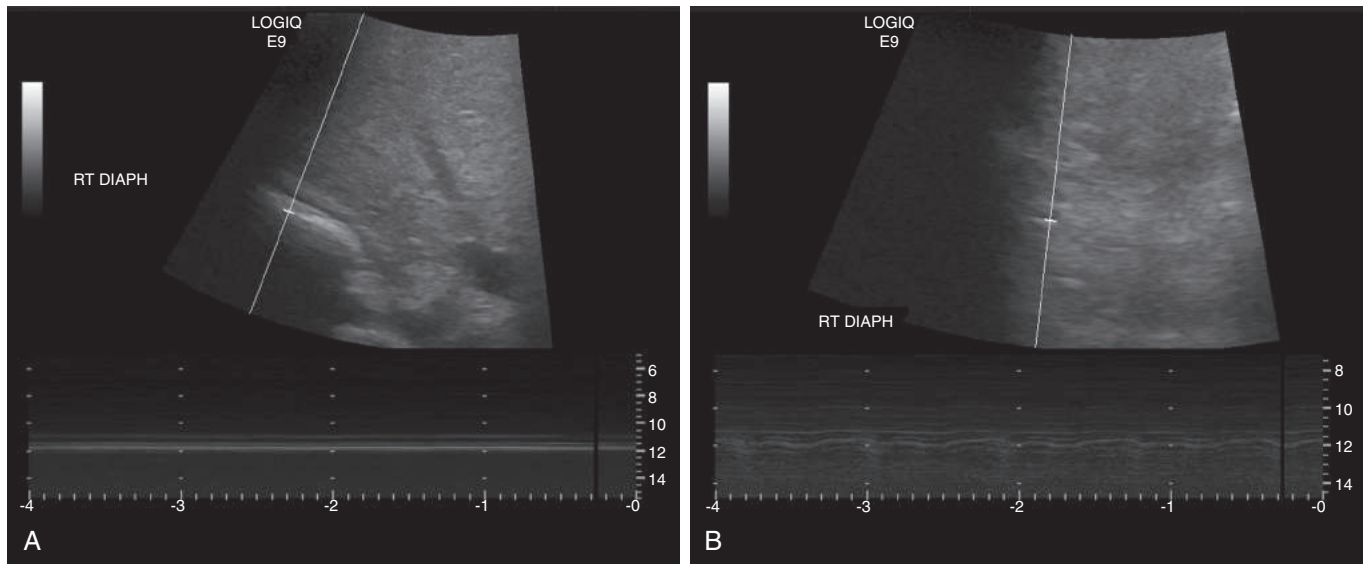

Approximately 18% of children with eventration have associated anomalies, with the most common being hypoplastic lungs, congenital heart disease, and pectus excavatum (Wu et al., 2015). With diaphragmatic eventration, movement of the hemidiaphragm is paradoxical, leading to respiratory distress, atelectasis, and recurrent pulmonary infections. Despite this, 50% of children with congenital eventration are without symptoms, making diagnosis difficult (Wu et al., 2015). Infants presenting later may have GI symptoms, and therefore early diagnosis and treatment are essential. Diagnosis is usually made by fluoroscopy of the chest, ultrasound of the diaphragm, or dynamic contrast-enhanced MRI. Small eventrations that are asymptomatic can be observed. Surgical intervention for symptomatic eventration involves plication of the diaphragm to eliminate the paradoxical movement. The diaphragm can be approached via the abdomen or chest using either open or laparoscopic/thoracoscopic techniques (Lao et al., 2013; Borruto et al., 2014). Results are generally good, with severe lung hypoplasia uncommon and improvement in symptoms without recurrence. However, infants with associated conditions, particularly neuromuscular disorders, may not survive. Some surgeons advocate plication, even when symptoms are not present, to preserve potential for lung growth (Tsugawa et al., 1997).

Diaphragmatic Paresis

Phrenic nerve injury because of birth trauma or surgical trauma can result in temporary paresis of the diaphragm, with an elevated hemidiaphragm and paradoxical movement evident by ultrasound or fluoroscopy (Fig. 49.14). If infants are persistently symptomatic, diaphragmatic plication may allow for weaning from mechanical ventilation or to lesser levels of respiratory support, but these injuries should also recover on their own over time (Wayne et al., 1974; Tsugawa et al., 1997).

Neonatal Scimitar Syndrome

Scimitar syndrome consists of three findings of right lung hypoplasia, partial anomalous pulmonary venous return, and unilateral pulmonary sequestration. These features may not all be present, and additional cardiac anomalies, including hypoplasia of the left heart or aorta, may also be detected (Gao et al., 1993). Scimitar syndrome can be suspected on fetal ultrasound, because of findings of cardiac dextroposition with a small right pulmonary artery (Abdullah et al., 2000). The presentation of scimitar syndrome in the first days after birth is usually severe, with tachypnea and pulmonary hypertension (Gao et al., 1993; Huddleston et al., 1999). Some infants will present later with failure to thrive. Chest radiograph reveals an elevated right hemidiaphragm with the mediastinum shifted to the right, consistent with primary lung hypoplasia. The classic finding of the scimitar vein is often not appreciated. Because these infants have a normally developed diaphragm, the surgical approach will depend on hemodynamic effects of the anomalous venous return and the sequestration (if present). Thus careful hemodynamic and vascular assessment are critical and may be accomplished through cardiac catheterization and angiography or, in some cases, by magnetic resonance angiography. Some infants will require pneumonectomy, others ligation or coil embolization of systemic feeding vessels, and others no intervention because the hypoplastic lung may have very little blood flow. Pulmonary vein stenosis can also complicate the hemodynamic status, and medical or surgical treatment for additional cardiac lesions may need to be addressed.

• **Fig. 49.14** Diaphragmatic Paresis. M mode ultrasound images of a newborn with tachypnea and moderate respiratory distress. (A) The absence of right diaphragmatic excursions is consistent with complete diaphragmatic paralysis. (B) The left diaphragm has low-amplitude excursions with normal inspiratory and expiratory motion. (Courtesy of Dr. Chirag V. Patel, Assistant Professor, University of California, Davis Health System, Department of Radiology, Sacramento, CA.)

Developmental Biology of the Heart

ELLEN DEES AND H. SCOTT BALDWIN

KEY POINTS

- The heart forms from cardiac mesoderm as a symmetric linear tube with connections to the primitive arterial and venous systems. The heart tube is formed by 3 weeks' gestation in the human.
- The heart tube loops, establishing laterality and undergoes septation into four chambers with connections to the systemic and pulmonary arteries and veins. The heart is fully formed by 9 weeks' gestation.
- External populations of cells migrate into the developing heart, making important contributions to the cardiac valves, coronary arteries, and cardiac chambers.
- Congenital heart malformations arise when these processes are altered or incomplete.

Overview of Cardiac Developmental Anatomy

This chapter will begin with a review of embryonic and fetal cardiac anatomy and of the cell types that make up the heart and will then discuss the morphology and physiology of the developing heart. We will mention certain genes that are important in cardiac development, although this is not a comprehensive review of the genetic regulation of heart development. Rather we will focus on aspects of heart development of particular interest to clinical neonatologists. These include the creation of inflow and outflow poles of the heart, alignment of these structures with the cardiac chambers, septation of the cardiac chambers, and the physiology of blood flow in the embryo, fetus, and newborn.

The heart begins as a field of cells (cardiac mesoderm) that moves ventrally and midline within the embryo, fusing into a tube. This primitive heart tube is formed in the human embryo by 3 weeks' gestation (Fig. 50.1, 21 days). At the posterior (dorsal) end of the tube is the venous pole, or sinus venosus. In mammals this includes connections to the yolk sac (vitelline veins), placenta (umbilical veins), and embryo proper (cardinal veins). At the anterior (ventral) end of the tube is the arterial pole, or bulbus cordis, which will pass flow from the heart tube back into the body. In the primitive heart this connection is to the aortic sac, which is connected to paired dorsal aortae. The heart tube itself is divided into an atrial segment adjacent to the venous pole, an atrioventricular

canal, and a ventricular segment adjacent to the arterial pole. Within the primitive heart tube, faint constrictions can be seen between these segments. Each of these segments is histologically and functionally distinct from the beginning: atrial and ventricular myocytes have distinct characteristics even when isolated from the primitive mesoderm. By the time the heart tube is formed, differentiating cardiomyocytes have generated functional contractile units mature enough to begin spontaneous contractions. These are initially peristaltic in nature, moving blood from venous inlet to arterial outlet.

Thus as soon as the heart forms, its primitive connections to the body are in place and its contractile function is operational, such that it pumps fluid to the rapidly growing embryo. Red blood cells begin to enter the circulation from blood islands in the yolk sac by the time the heart starts to beat at 22 days' gestation (Carlson, 2004). For the first 6 weeks the yolk sac remains the exclusive source of hematopoietic cells, until the liver (and to a lesser extent spleen) takes over. The bone marrow gradually becomes populated with hematopoietic cells beginning in the second trimester of pregnancy and by birth is the major source of blood cells (Carlson, 2004). Development of a circulatory system early is critical to maintaining nutrition and oxygen delivery to developing tissues, which are at this point beyond the ability to depend on simple diffusion of nutrients.

From the primitive heart tube state the heart undergoes significant growth and morphologic alterations. These include establishing laterality, such that the symmetry of the heart tube is lost and there are well-defined left and right structures within the heart and vessels. As laterality is being established the heart undergoes a dramatic change in shape, via a process known as *cardiac looping*. This occurs in the human embryo during week 4 of gestation (Fig. 50.1, 25–28 days). From this stage, the heart realigns its inflow and outflow segments, undergoes septation, and forms valves in processes that will be detailed in this chapter. The “final product” will be a mature heart (Fig. 50.1, bottom) with the following structures:

1. A *venous pole* or *sinus venosus* that is now connected to systemic veins from the upper body (superior vena cava [SVC]), lower body (IVC), liver (hepatic veins), and coronary circulation (coronary sinus), all of which pass into the *right atrium*.
2. A separate *left atrium*, connected to the venous system separately by ingrowth of *pulmonary veins* from the lungs.

• **Fig. 50.1** (Top) Morphology of the human heart at 3 to 5 weeks' gestation. Orientation in the body as shown, with cranial–caudal (*cr*, *ca*), dorsal–ventral (*d*, *v*), and left–right (*l*, *r*) planes. The heart tube is initially linear, with the inflow region dorsal/caudal and the outflow region ventral/cranial. During week 4 the heart undergoes looping, realigning the segments such that the inflow is shifted dorsal/leftward, and the outflow is shifted ventral/rightward. After looping the atrial and ventricular segments are approximately on the same plane in the cranial/caudal axis. (Bottom) A scanning electron micrograph of a human heart at 9 weeks' gestation, after looping, and after septation of the atria, ventricles, and great arteries. ([Top] From Carlson BM. *Human Embryology and Developmental Biology*. 4th ed. Philadelphia, PA: Mosby; 2009:457. [Bottom] From Steding G. *The Anatomy of the Human Embryo*. Basel, Switzerland: S. Karger; 2009:215.)

3. An *AV canal* that begins as a single unrestricted opening and undergoes septation into two AV valves. The *tricuspid valve* opens from the right atrium into the right ventricle (RV), and the *mitral valve* opens from the left atrium into the left ventricle (LV).
4. A *primitive ventricle* that has expanded and undergone septation into two distinct and separate chambers, a *right* and an *LV*. By processes known as *compaction* and *trabeculation*, the working myocardium of each ventricle has become highly organized and adapted to the unique requirement of a pulmonary (right) or systemic (left) ventricle.
5. An *arterial pole*, or *bulbus cordis*, that forms the two separate outflow tracts of the heart. The distal part of the bulbus cordis is the *arterial trunk*, which undergoes septation in a spiral fashion, creating an anterior *pulmonary artery* connecting to the lungs and a posterior *aorta* connecting to the body. The proximal part of the bulbus cordis is the *conus*, which is retained by the RV. At the junction between the conus and the pulmonary artery, the *pulmonary valve* forms. The *aortic valve* forms at the junction between the LV and the aorta.
6. Paired *dorsal aortae* connected to the *aortic sac* that have undergone extensive remodeling into a single leftward *aortic arch* and *descending aorta*. This connects proximally to the *coronary arteries*, the head and neck arteries, and to a temporary structure important in fetal life, the *ductus arteriosus*.
7. Networks of coronary arteries that have formed within the myocardium of the heart. These connect to the aorta as the right and left coronary arteries.
8. Networks of myocytes that have differentiated into the conduction system of the heart, including the sinoatrial node, the AV node, and the His–Purkinje system of the ventricles.

Cell Types Within the Heart and Their Origins

The mature heart has three cell layers: the endocardium, an epithelial lining one cell layer thick; the myocardium, a precisely oriented network of myocytes that perform the contractile work of the heart; and the epicardium, an epithelium that covers the external surface of the heart. Beyond this the heart resides within a pericardial sac, similar in composition and function to the pleura, which covers the lungs.

Much, but not all, of the heart has its embryonic origin from a field of lateral plate mesodermal cells referred to as the *cardiogenic mesoderm* (Fig. 50.2; orange/red). The primitive heart tube forms as a two-layer structure, with an endocardium and a myocardium, both cell types coming from cardiac mesoderm. The endocardium remains as an epithelium, but a subset of cells delaminates and invades the proteinaceous matrix between the endocardium and myocardium to form the endocardial cushions. These cells will be vital to proper valve development and to complete septation of the atria and ventricles. The myocardium primarily remains muscle, but a subpopulation of the cells also change course and differentiate into Purkinje fibers of the conduction system.

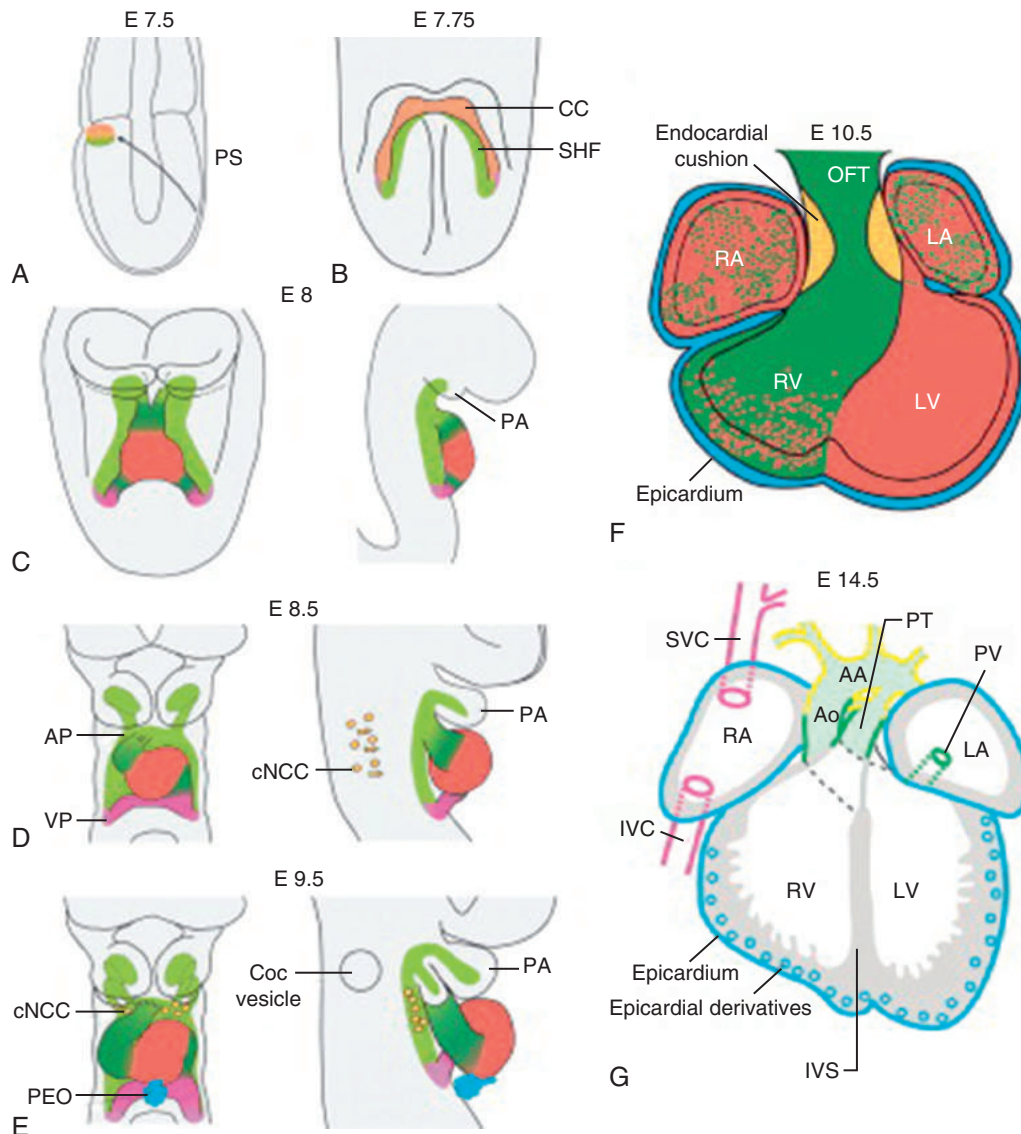

The outflow tracts of the heart are arguably the most complex genetically and morphologically and thus most prone to developmental defects. The secondary heart field is a population of cardiac mesoderm anterior and medial to the original heart field that migrates to the heart after formation of the primitive heart tube (see Fig. 50.2; green). It contributes significantly to the RV and outflow region of the heart, as well as to the ventricular septum

and probably parts of the atria (Mjaatvedt et al., 2001; Waldo et al., 2001; Kelly and Buckingham, 2002; Christoffels et al., 2006). The secondary heart field was primarily discovered in cell lineage tracing studies. In chick hearts marked just after fusion of the heart tube, a population of unmarked cells interposed themselves between marked cells of the distal part and middle part of the heart tube 1 day later (Mjaatvedt et al., 2001). Studies in the mouse compared with the chick suggest that the anterior heart field in the mouse forms most of the RV (Kelly and Buckingham, 2002; Zaffran et al., 2004). What differences there are in humans remain unknown. Genetically, the secondary heart field is characterized by markers, including *Tbx1*, *Isl1*, *Mef2c*, *Tbx20*, and *Aldh1a2*; knockout of any of these genes in the mouse causes outflow tract septation defects (Jerome and Papaioannou, 2001; Merscher et al., 2001; Niederreither et al., 2001; Cai et al., 2003; Dodou et al., 2004; Takeuchi et al., 2005). Further, it has been shown that as the secondary heart field cells move into the outflow tract of the heart, they lose many of their original genetic markers and express myocardial markers such as *Hand1*, *Nkx2-5*, *Tbx5*, *Gata4*, and *Mef2c* (Dodou et al., 2004; Verzi et al., 2005; Waldo et al., 2005b; Ward et al., 2005; Zeisberg et al., 2005; Dyer and Kirby, 2009). These are factors already well studied in the primary heart field known to contribute to myogenesis and cardiac looping (Srivastava et al., 1997; Hiroi et al., 2001; Jamali et al., 2001b; Fijnvandraat et al., 2003; Garg et al., 2003; Han and Olson, 2005; McFadden et al., 2005; Han et al., 2006; Maitra et al., 2009). Defects in expression of these genes in the secondary heart field can lead to right-ventricular hypoplasia and outflow tract abnormalities, including tetralogy of Fallot (Ward et al., 2005; Zeisberg et al., 2005).

In addition to cells from the secondary heart field, neural crest cells are an important population that migrate into the developing outflow tract (see Fig. 50.2; yellow). Neural cells originate in the anterior rhombencephalon and migrate as a sheet through the pharyngeal region and into the aortic arches (Waldo and Kirby, 1993; Waldo et al., 1996; Creazzo et al., 1998; Epstein et al., 2000; Li et al., 2003). The neural crest cells surround the epithelia of the arch arteries and extend into the truncus and proximal conus. Here they interact with endocardial cushion cells to cause the great arteries to undergo septation and close the conal septum (Kirby et al., 1983). These neural crest cells are also important to development of the nearby parathyroid, thyroid, and thymus glands. They also innervate the heart and form much of the smooth muscle of the proximal aorta (Creazzo et al., 1998).

Yet another external population of cells that makes important contributions to the mature heart is a cluster of cells that forms dorsal and inferior to the heart tube known as the *proepicardial organ* (see Fig. 50.2; blue) (Nahirney et al., 2003; Ishii et al., 2007). The origin of these cells is a subject of debate; one leading theory is that they are derived from liver primordium (Ishii et al., 2007). These cells expand as an epithelial sheet covering the surface of the heart to form the epicardium. From the epicardium, subgroups of cells delaminate and migrate into the myocardium beneath in a process known as *epithelial to mesenchymal transformation*. These cells differentiate into vascular smooth muscle, vascular endothelial cells of the coronary arteries, and cardiac fibroblasts, which make up a sizable population of cells residing within the myocardium, between myofibers.

Thus in addition to cardiomyocytes arising from at least two populations of mesoderm, the heart is composed of cells from epithelial and neural crest origins that migrate in with spatial and temporal precision during cardiac development. The next several sections will highlight the steps of this process.

• **Fig. 50.2** The cell types of the heart. The cardiac crescent (first heart field, *orange*) forms as cells migrate anteriorly from the primitive streak at gastrulation. The second heart field (*green*) forms medial to the cardiac crescent (A, B). These cells go on to form the four chambers of the heart and inflow and outflow tracts as shown (C–F); primary heart field derivatives are in *red* and secondary heart field derivatives in *green*. There are also important contributions to the developing heart from cardiac neural crest cells (*yellow*) and the proepicardium (*blue*) (G). Embryonic stages shown are for the mouse. AA, Aortic arch; Ao, aorta; AP, arterial pole; CC, cardiac crescent; cNCC, cardiac neural crest cells; E, embryonic day; IVC, inferior vena cava; IVS, interventricular septum; LA, left atrium; LV, left ventricle; OFT, outflow tract; PA, pharyngeal arch; PEO, proepicardial organ; PS, primitive streak; PT, pulmonary trunk; PV, pulmonary vein; RA, right atrium; RV, right ventricle; SHF, secondary heart field; SVC, superior vena cava; VP, venous pole. (From Vincent S, Buckingham M. How to make a heart: the origin and regulation of cardiac progenitor cells. *Curr Top Devel Biol.* 2010;90:1–41.)

Formation of the Embryonic Cardiac Crescent and Heart Tube

Most of what is known about the early stages of embryonic development comes from extensive studies of avian and mouse models (Garcia-Martinez and Schoenwolf, 1992, 1993; Melnik et al., 1995; Yutzey and Bader, 1995; Baldwin, 1996; Fishman and Chien, 1997; Baldwin, 1999; Redkar et al., 2001; de Lange et al., 2004; Abu-Issa and Kirby, 2007; Combs and Yutzey, 2009; Cui et al., 2009; Dyer and Kirby, 2009). This is extended, with

some acknowledged gaps, to human development. In its earliest stages the embryo exists as a bilayer disk of two epithelial sheets of cells suspended between two fluid-filled cavities, the yolk sac and the amniotic cavity. The ventral layer (facing the yolk sac) is the hypoblast, which will eventually be relegated to extraembryonic structures. The dorsal layer (facing the amniotic cavity) is the epiblast, which will actually form all three embryonic germ layers: the ectoderm (nervous system and skin), mesoderm (heart, skeleton, muscle, and connective tissue), and endoderm (gut). Mesoderm and embryonic endoderm separate from the primitive ectoderm

• **Fig. 50.3** Gastrulation and the formation of the three germ layers, A–C. Cardiomyocytes originate from mesodermal precursors (red and green). The heart tube fuses as it is displaced ventrally and to the midline by the folding gut tube (blue). (From Mikawa T. Cardiac lineages. In: Harvey R, Rosenthal N, eds. *Heart Development*. New York, NY: Academic Press; 1999:19–33.)

by a process known as *gastrulation* (Fig. 50.3A). Gastrulation begins as a groove forms in the epiblast starting at the tail end (caudal) and gradually extending cranially to an end point known as the prechordal plate. The groove is known as the *primitive streak*, and its leading edge is known as the *primitive node*. Along the primitive streak, epiblast cells delaminate from the epithelial sheet and invade the potential space between the epiblast and hypoblast. The heart forms as a crescent of cells cranial to the prechordal plate and extending along both sides. Fate-mapping studies suggest that many cell fate decisions may be set during gastrulation or even before (Garcia-Martinez and Schoenwolf, 1993; Fishman and Chien, 1997). For example, within the cardiac crescent, the apex of the crescent is formed from cells that have migrated through the

primitive streak closest to the primitive node and contains precursors of the outflow tract myocardium. The cells on either side of this region have migrated through the midportion of the streak and are ventricular myocyte precursors. Finally, the most lateral and caudal cells are those that have migrated through the most posterior part of the streak and will become atrial myocytes. The exact details of when and how this occurs are still under debate and refinement as better techniques become available (Ehrman and Yutzey, 1999; Abu-Issa and Kirby, 2007; Cui et al., 2009). Fate-mapping studies using live-cell tracking and time-lapse imaging demonstrate that these cells move as a cohort (tissue motion) rather than migrating individually; this is a way to maintain cells' relative positions within a tissue and, eventually, an organ (Cui et al., 2009).

Looping and Laterality of the Heart Tube

The cardiac crescent is a symmetric structure and fuses into an initially symmetric appearing heart tube. This occurs as the ectoderm dorsal to the crescent is folding to create the neural canal, and the endoderm initially ventral to the crescent is folding to create the foregut (see Fig. 50.3B). As the foregut forms, it moves dorsally, pushing the cardiac crescent ventrally and medially, such that the two arms of the crescent fuse into a tube sitting directly in front of the foregut (see Fig. 50.3C). As fusion of the heart fields occurs, the heart is already beating. In a human fetus this happens at approximately 22 days' gestation. During the next week there is tremendous growth of the head, such that the heart goes from being the most "cranial" structure in the embryo to a position tucked underneath the developing head of the embryo.

As the head grows up and over the heart tube, the heart tube itself begins to undergo a dramatic change in shape known as *looping*. Here the heart tube loses its symmetry, and distinct left and right morphology can be identified (Steding, 2009). Much is known about the molecular signaling and gene expression patterns involved in looping. The basic left–right asymmetry of the embryo is set during gastrulation by concentration gradients of the factors sonic hedgehog and fibroblast growth factor 8. This gradient is created by ciliary motion at the primitive node and causes a cascade of downstream genes to be activated, including *Nodal*, *Lefty1*, and *Pitx2* (Tsukui et al., 1999; Capdevila et al., 2000; Rodriguez-Esteban et al., 2001). Within the heart tube, several cardiac transcription factors have been shown to be important to looping, including *Nkx2-5*, myocyte enhancer factor 2, and heart and neural crest derivatives expressed 2 (Srivastava et al., 1997; Tsukui et al., 1999; Hiroi et al., 2001; Jamali et al., 2001a, 2001b; Yamagishi et al., 2001; Han and Olson, 2005; McFadden et al., 2005; Christoffels et al., 2006; Han et al., 2006; Karamboulas et al., 2006; Cui et al., 2009). Disruption of any of these factors in mice by gene knockout causes embryonic lethality, with a block in heart development at the looping stage. Morphologically, cardiac looping involves differential growth, with higher proliferation of myocytes along the outer curvature than along the inner curvature (Moorman and Christoffels, 2003), along with a substantial migration of cells from the secondary heart field (Kioussi et al., 2002). All of this serves to elongate the outflow tract and enlarge the ventricles relative to the atria (Moorman and Christoffels, 2003). In addition, there are mechanical forces pulling, twisting, and realigning structures of the primitive heart tube. This is thought to involve the cytoskeleton, including nonmuscle myosin (Linask and Vanauker, 2007), the motor protein dynein (Supp et al., 1997; Brueckner, 2001; Basu and Brueckner, 2008), microtubules (Icardo and Ojeda, 1984), and nonmuscle actin bundles (Itasaki et al., 1991).

• **Fig. 50.4** (A) Normal cardiac D-looping with normal atrioventricular (AV) connections. Also shown are several common abnormal looping patterns, including mirror-image L-looping with normal AV connections (B), discordant AV connections with atrial situs inversus (C), and discordant AV connections with normal atrial situs (D). Both discordant AV connections with atrial situs inversus and discordant AV connections with normal atrial situs are usually associated with discordant ventriculoarterial connections, creating congenitally corrected transposition. Right- and left-atrial isomerism, or bilateral right sidedness (E) and bilateral left sidedness (F), generally found along with anomalies of the systemic and pulmonary veins, of cardiac septation, and of the inflow and outflow tracts. Right and left isomerization syndromes also go along with abnormal sidedness on other asymmetric organs of the chest and abdomen, or heterotaxy. (G) Normal visceral organ arrangement, (H) mirror image, or situs inversus, (I) right isomerism, and (J) left isomerism. The numbered segments 1,2 and 1,2,3 refer to the lobes of the left and right lungs. (Modified from Brown NA, Anderson RH. Symmetry and laterality in the human heart: developmental implications. In: Harvey R, Rosenthal N, eds. *Heart Development*. New York, NY: Academic Press; 1999:447–461.)

Normal looping occurs to the right (D-looping); that is, the sinus venosus and atria move toward the left and posteriorly, and the ventricles and bulbus cordis move to the right and anteriorly. Importantly, the venous pole also moves cranially such that it lines up with the arterial pole along the horizontal body axis. This is seen in Fig. 50.4A. The bulbus cordis remains to the right of the primitive ventricle. This repositioning is critical for proper AV and ventriculoarterial connections. Also with looping, an outer curvature and an inner curvature of the heart are established. The anterior outer curvature is an area of rapid myocardial growth and expansion to form the ventricular chambers. The posterior inner curvature undergoes slower growth and acts rather like a fulcrum for the looping process. The inner-curvature myocardium contributes to the AV canal and is critical to the formation of the endocardial cushions.

Abnormalities in Cardiac Looping

Sometimes, looping can occur to the left, with the venous pole and atria moving rightward and the ventricles and arterial pole moving leftward (see Fig. 50.4B). This is referred to as *L-looping*. If there is complete mirror imagery, the cardiac connections are completely normal with dextrocardia. Often, however, there are both AV and ventriculoarterial discordance, an entity referred to as *congenitally corrected transposition*. Here the atrial situs is usually normal, but the ventricles loop to the left, and the bulbus cordis ends up to the left of the primitive ventricle (see Fig. 50.4D). When the great arteries undergo septation, there is L malposition of the great arteries, so the aorta is to the left of the pulmonary artery (parallel, not crossed). The resulting circulation is as follows: right atrium to LV to pulmonary artery; left atrium to RV to aorta.

In isolation, this defect allows normal circulation, although with the RV, which is structured to pump to the low pressure pulmonary circulation, as the systemic ventricle. Alternatively, this physiology can occur with atrial situs inversus and D looping of the ventricles with D malposition of the great arteries (see Fig. 50.4C). Often there are additional cardiac defects, ranging from a ventricular septal defect (VSD) with pulmonary valve stenosis to more complex defects involving hypoplasia of one of the ventricles or hypoplasia, aplasia, or malformation of one or more valves.

L-looping may also be associated with more global defects known as *heterotaxy syndromes*. Heterotaxy syndromes are a heterogeneous group of congenital defects, with the commonality being abnormal left–right asymmetry of the embryo (Ghosh et al., 2009). In heterotaxy, left–right assignments along the body axis are randomized. Thus it is possible to have mirror-image asymmetry, or bilateral symmetry, with either two right sides or two left sides. This is often termed *right isomerism* or *left isomerism* (see Fig. 50.4E–F and I–J). This can affect the abdomen, lungs, and heart. In the abdomen the gut, liver, and spleen may be reversed from normal (abdominal situs inversus). There may be malrotation of the bowel and anomalies of the biliary tree. The spleen, being a normally left-sided structure, can be duplicated in left isomerism (polysplenia) and absent in right isomerism (asplenia). Asplenic patients require antibiotic prophylaxis in childhood to protect against bacterial infections. Asplenic patients usually have left isomerization of the lungs and heart as described later; polysplenic patients have right isomerization of the lungs and heart. Lung abnormalities in heterotaxy manifest themselves in the bronchial and lung anatomy. The normal left lung is bilobed, and the left main bronchus travels beneath the left pulmonary artery (hyparterial). The normal right lung is trilobed, and the main bronchus travels above the right pulmonary artery (eparterial). Thus careful examination of a chest X-ray in left isomerism reveals bilateral hyparterial bronchi and in right isomerism shows bilateral eparterial bronchi.

In the heart the atrial sidedness is randomized in heterotaxy. Here the atria may be normal (situs solitus), left–right reversed (situs inversus), or unclear (situs ambiguous; including bilateral right atria or bilateral left atria). The atria are most practically defined by their venous return, systemic to the right atrium and pulmonary to the left. But in heterotaxy this is not always possible, as the pulmonary or systemic veins may return to both atria. The pulmonary veins grow in from the developing lungs normally joining the back wall of the left atrium. When the left–right cues are scrambled, the pulmonary veins often return ipsilaterally: left-sided veins to left-sided atrium and right-sided veins to right-sided atrium. Likewise, the systemic veins may return to either atrium or both atria in heterotaxy (e.g., a right SVC to the right atrium and a left SVC to the left atrium). This is because the systemic veins start out as paired symmetric structures (see [Systemic and Pulmonary Vein Development](#)), with involution of certain structures occurring as part of the establishment of left–right asymmetry in the embryo. Finally, certain patterns of additional cardiac defects often accompany asplenia/right isomerism. These include failure of septation of the ventricles, resulting in a single ventricle, pulmonary underdevelopment (stenosis or atresia of the pulmonary valve), bilateral superior venae cavae, and anomalous pulmonary venous return. For polysplenia/left isomerism, commonly associated defects include endocardial cushion defects (see later), left-sided obstructive lesions such as coarctation of the aorta, and interruption of the inferior vena cava (IVC) with azygous continuation to the SVC.

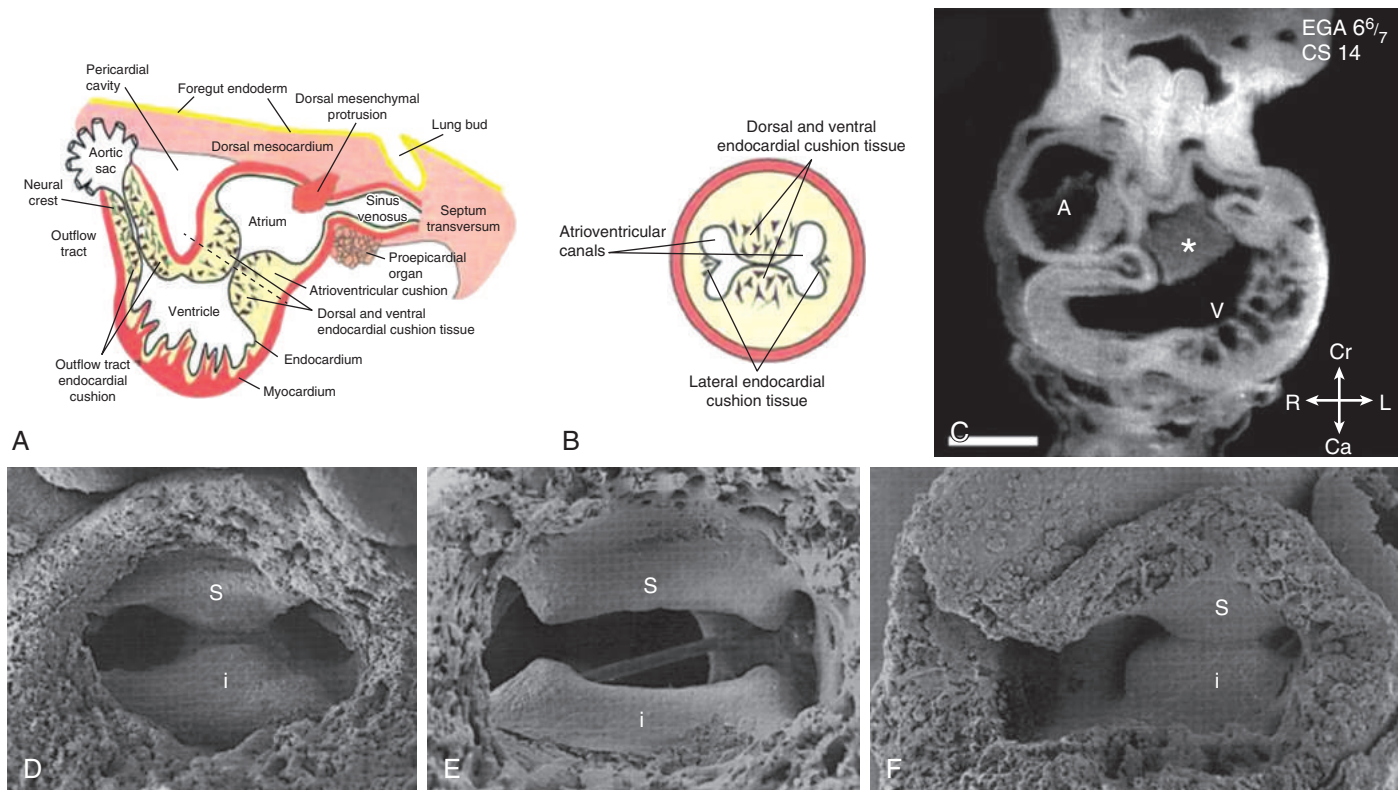

Ventricular Inlet Septation: Endocardial Cushions

After cardiac looping has occurred, the orientation of the heart tube has changed drastically, but the progression of blood flow through it remains in essentially the same sequence: into the heart from the venous pole, through the common atrium into the common ventricle, and out the conotruncus to the aorta. Inflow and atrial segments are leftward, and the ventricle and outflow are to their right. If the process arrests near this point, a heart may form with its entire inlet portion aligned over the leftward ventricle (a double-inlet LV) or with its entire outlet portion aligned over the rightward ventricle (a double-outlet RV). Both of these entities are seen in humans. What is very rarely seen is a double-inlet RV, or a double-outlet LV: even if there is L-looping and/or dextrocardia, this basic sequence is maintained.

During the next phase of heart development, the AV (inlet) and ventriculoarterial (outlet) structures will realign and undergo septation, such that there is a valved inlet and a valved outlet for each ventricle. In human embryos this occurs during week 7 of gestation (Dhanantwari et al., 2009; Steding, 2009). These valves are formed primarily from the endocardial cushions. The endocardial cushions are also critical to complete ventricular and atrial septation, completing the portions of septum adjacent to the AV valves. This will be detailed further in sections on atrial and ventricular septation. Thus the endocardial cushions form the crux of the heart: a point in the center of the heart at which separate AV canals are to the left and right, and atrial and ventricular septa are aligned above and below.

Within the primitive heart tube, even before looping, there are faint constrictions at the AV groove and in the forming conotruncus (see Fig. 50.4). The endocardial cushions initially appear as swellings in the AV and conotruncal segments of the primitive heart, by 6 weeks' gestation (Fig. 50.5A and C). The swellings are caused as cells from the inner lining of the heart (endocardium) delaminate and migrate into the extracellular matrix in between the endocardium and the myocardium. Signaling involving the transforming growth factor β (TGF- β) family between the myocardium and endocardium plays a crucial role in initiating and maintaining this process (Brown et al., 1996, 1999; Jiao et al., 2006). The delaminating cells change phenotype in a process known as *epithelial to mesenchymal transformation*. The cells lose their epithelial, or sheetlike, characteristics and acquire a mesenchymal phenotype, losing junctions with neighboring cells, invading the matrix, and proliferating faster (Kim et al., 2001; Lincoln et al., 2004; Shelton and Yutzev, 2007; Combs and Yutzev, 2009). Why some cells respond to such signals to undergo epithelial to mesenchymal transformation but neighboring cells remain epithelial is unclear.

In both the AV canal and the conotruncus, four distinct cushions form, named by their anatomic locations. For the AV canal these are superior (ventral), inferior (dorsal), left lateral, and right lateral (see Fig. 50.5B). In the conotruncus they are right superior, right dorsal, left inferior, and left ventral. The AV and conotruncal cushions are separate, with one important exception: the left ventral conal cushion and the superior AV cushion are in continuity along the inner curvature of the heart (see Fig. 50.5A). This proximity will persist in the fully septate heart as aortic–mitral valve continuity. The AV canal undergoes septation as the superior and inferior cushions grow and extend (see Fig. 50.5D–F), finally fusing in the midline. This results in complete separation of the AV canal into left (mitral) and right (tricuspid) sides. The AV valves form from remnants of the cushions: a leftward mitral valve with two leaflets and a rightward tricuspid valve with three leaflets.

• **Fig. 50.5** Formation of the endocardial cushions. (A) Cushion formation in the inflow and outflow tracts by epithelial to mesenchymal transition in the looped heart tube. Also shown are the neighboring tissues and cell populations contributing to the developing heart at this stage. (B) Atrioventricular canal undergoing septation. (C) An episcopic fluorescence image capture image of a sectioned paraffin-embedded human embryo at 6½ weeks. Seen are atria (A), ventricles (V), and atrioventricular cushions (asterisk). Scale bar 0.515 mm. (D–F) Scanning electron micrographs of human embryos at 6 weeks' gestation, showing the superior (S) and inferior (i) atrioventricular cushions, with the tricuspid (left) and mitral (right) orifices. Ca, Caudal; Cr, cranial; L, left; R, right. ([A, B] From Schoenwald GC, Bleyl SB, Brauer PR, Francis-West PH. *Larsen's Human Embryology*. 5th ed. Philadelphia, PA: Churchill Livingstone; 2015:267–303. [C] From Dhanantwari P, Lee E, Krishnan A, et al. Human cardiac development in the first trimester: a high-resolution magnetic resonance imaging and episcopic fluorescence image capture atlas. *Circulation*. 2009;120:343–351. [D–F] From Steding G. *The Anatomy of the Human Embryo*. Basel, Switzerland: S. Karger; 2009:221.)

Failure of complete fusion between the superior and inferior cushions in the midline results in a cleft within the anterior leaflet of the mitral valve. This is a mild form of an endocardial cushion defect, often associated with a primum atrial septal defect (ASD) (see [Development of the Atria and Atrial Septum](#)) and known as a *partial AV canal*. The septal leaflet of the tricuspid valve also forms from these superior and inferior cushions and can be abnormal as well although this is less often clinically significant. More profound failure of proper AV cushion expansion and fusion results in a complete AV canal. Here the crux of the heart is unformed. There remains a common orifice overlying both ventricles, with defects in the adjacent atrial and ventricular septa. The common AV valve has a leaflet structure based on the nonseptate AV canal, with four or sometimes five separate leaflets corresponding to the two lateral leaflets, the superior (referred to as *anterior bridging*) and inferior leaflets.

The AV canal myocardium, part of the primitive heart tube, does not persist in the adult heart. There is no muscular connection between the mature atria and ventricles. The process for isolation of the atrial and ventricular muscle appears to occur as the

epicardium of the AV sulcus establishes continuity with the developing endocardial cushions beneath; this occurs all along the ventricular margin of the AV canal (Wessels et al., 1996). The only remaining connection that remains between the atria and the ventricles is within the conduction system, the AV node (Anderson and Ho, 1998; Anderson et al., 2000; Anderson and Ho, 2003). Occasional muscular bridges of tissue remain as accessory muscle connections, which can be clinically important as a substrate for arrhythmias (specifically AV reciprocating tachycardia, a common form of supraventricular tachycardia).

Ventricular Outflow Tract Septation: Endocardial Cushions and Neural Crest

While the AV cushions form a three-dimensional crux of the heart, the conotruncal cushions form a three-dimensional spiral, completing an almost 180-degree rotation (Ya et al., 1998; Carlson, 2004). During septation of the outflow tracts, the primitive bulbus cordis is separable into two segments, the truncus adjacent to the aortic

• **Fig. 50.6** Septation of the outflow tracts. (A) Contribution of neural crest (blue, *a*) migrating into secondary heart field (SHF; red, *b*) in developing outflow tracts in the mouse embryo; the arches are numbered 1–6. The schematic (*c*) shows the extent of these tissues, as well as the contribution from conal endocardial cushions (green). (B) Episcopic fluorescence image capture image of an embryo at 8 weeks' gestation showing left ventricle (LV) and developing left ventricular outflow tract (LVOT) and the anterior right ventricle (RV) and a portion of the pulmonary artery (PA). Scale bar 1.35 mm (C, D). Tie2 Cre LacZ staining in mouse embryos showing extent of endocardial cushions, first in the conal myocardium at embryonic day 10.5 and extending into the outflow tracts undergoing septation by embryonic day 11.5. sac and the conus adjacent to the ventricular myocardium (Fig. 50.6A). The right superior and left inferior cushions are within the truncal region and will contribute to the aorticopulmonary septum. The right dorsal and left ventral cushions are within the conus region and are important for pulmonary and aortic valve formation and for completion of septation between the ventricles at the level of the pulmonary and aortic valves (Waldo et al., 2005b; Brown and Baldwin, 2006). The interface between the two sets of cushions is a critical region for formation and remodeling of the ventricular outflow tracts (Waldo et al., 2005a; Brown and Baldwin, 2006; Wu et al., 2011).

Again for this process to occur correctly, the continuity of the superior AV cushion and left ventral conus cushion is critical. To align the septate great arteries directly over the ventricles, the arterial trunk must shift to the left. There is evidence from mouse models that failure to achieve continuity of the superior AV cushion and left ventral conus cushion results in malalignment of both great arteries over the RV, along with a VSD (van den Hoff et al., 1999; Waller et al., 2000). Clinically, this is an entity known as *double-outlet right ventricle* (DORV). Part of the clinical definition of a DORV is the presence of a conus segment of both ventricles (bilateral conus). Anatomically, the normal conus is a muscular “neck” within the RV between the tricuspid and pulmonary valves. Embryologically, this is a remnant of the conus of the primitive heart tube that is retained by the RV. In the LV the fusion of the superior AV and left ventral conal cushions results in mitral–aortic continuity and lack of a conal segment. If this fusion of cushions and leftward shifting of the truncus do not occur, then a conus is retained in the left-ventricular outflow tract, which is malpositioned to the right.

In addition to their role in development of the conus of the heart and the semilunar valves, neural crest cells play a more global role in development of the head and neck structures. Migrating neural crest cells are also important to development of the parathyroid, thyroid, and thymus glands (Creazzo et al., 1998). Extensive work has been done in chick models with use of neural crest ablation, and these show a very high prevalence of persistent truncus arteriosus, interrupted aortic arch, tetralogy of Fallot, double-outlet RV, and VSDs, along with abnormal parathyroid, thyroid, and thymus development (Nishibatake et al., 1987; Waldo and Kirby, 1993; Kirby and Waldo, 1995; Waldo et al., 1996; Creazzo et al., 1998). In human DiGeorge syndrome, cardiac conotruncal and arch defects are associated with developmental defects in each of these three glands as well. A deletion of up to 3 megabases in chromosome 22 (22q11) has long been known to be associated with DiGeorge syndrome, on the basis of kindred studies in families with the syndrome (Epstein, 2001; Merscher et al., 2001; Beaujard et al., 2009; Portnoi, 2009). In humans the defect is autosomal dominant, with variable penetration, meaning that one copy of the gene deletion is sufficient to cause disease and that the disease severity varies from family member to family member. A similar deletion generated experimentally in mice yielded a model of the cardiovascular features of DiGeorge syndrome (Lindsay et al., 2001). *Tbx1* has been identified as the gene responsible in these mice (Jerome and Papaioannou, 2001; Lindsay et al., 2001; Merscher et al., 2001). T-box 1 is a transcription factor in a family known to be important in embryonic patterning. Homozygous mutations of *Tbx1* caused obliteration of the third, fourth, and sixth pharyngeal arches with embryonic lethality and caused most of the extracardiac defects as well, along with an abnormal ear, jaw, and pharynx (Jerome and Papaioannou, 2001). Heterozygous mutants, which are analogous to the human disease state, showed more variable

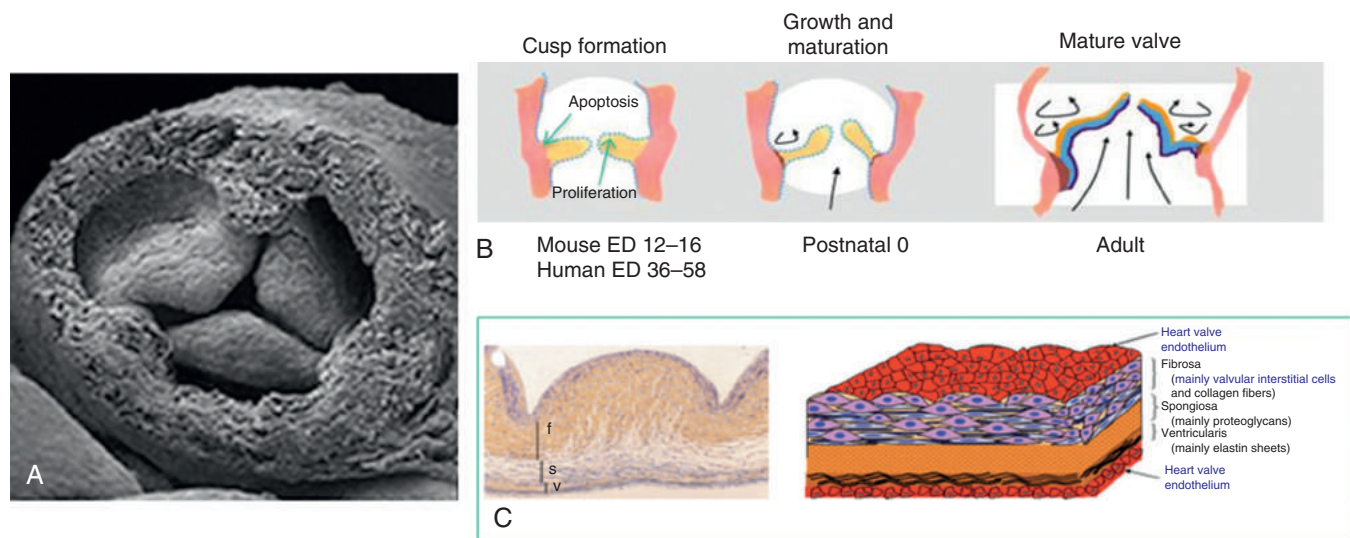

disease. The cardiac defects primarily affected the fourth pharyngeal arch and caused abnormal patterning of the great arteries in 50% of embryos in one study (Lindsay et al., 2001). This group had one heterozygous mouse mutant among 14 that also exhibited parathyroid and thymic insufficiency. Possibly, humans are more sensitive to gene dosage and exhibit the full range of defects in the haploinsufficient state. There may be other modifying genes as well, as there seems to be an important contribution of genetic background to the phenotype in mice, with more severe arch anomalies occurring in more inbred strains (Jerome and Papaioannou, 2001). This is a confounding factor of many gene targeting strategies and perhaps a clue as to why significant phenotypic variation can occur in humans with identical mutations. Isolated *TBX1* mutations appear to be very rare as causes of clinical DiGeorge syndrome (Beaujard et al., 2009; Portnoi, 2009; Rauch et al., 2009), most patients having a larger megabase deletion. Furthermore, *TBX1* expression is not found in neural crest cells themselves but rather in the secondary heart field, further highlighting the importance of interaction between these two cell populations in outflow tract development (Vitelli et al., 2002; Liao et al., 2008). Overexpression of *Tbx1* in mouse models is also associated with conotruncal defects, suggesting that there are critical levels of *Tbx1* expression necessary for proper outflow tract development (Liao et al., 2004; Liao et al., 2008).

Separation of Aorta and Pulmonary Artery: Normal Dextroposition

Within the truncus segment, septation also occurs during remodeling of the conus. This normally occurs as the truncal cushions fuse in a spiral fashion. Starting at the level of the AV valves, the newly forming pulmonary artery is directly anterior to the aorta. Further along the outflow tract, the pulmonary artery and aorta are more left–right to one another, as the spiral extends. As the aorta arches to the left, the proximal transverse arch passes anterior to the pulmonary artery, completing a 180-degree turn of the spiral. This sequence is seen in Fig. 50.6C–F. This rotation involves not only the truncal cushions but also the rotation of the myocardial tube (Lomonico et al., 1986; Bajolle et al., 2006). If this 180-degree twist does not occur or is incomplete, the result is transposed great arteries. This is defined by the aortic valve being anterior to the pulmonary valve. The left–right orientation of the valves is most commonly preserved (aortic rightward), although it can be within a 90-degree range from directly anterior–posterior to directly side-by-side. L-transposition, aortic leftward, is most often associated with L-looped ventricles or heterotaxy syndromes and is rare in isolated transposition. TGF- β signaling, important in left–right patterning and extracellular matrix remodeling and many other processes in normal development, appears to play an important role in this process both in mouse models and in human disease (Oh and Li, 1997; Rankin et al., 2000; Goldmuntz et al., 2002; Karkera et al., 2007).

Cardiac Valve Formation

Cardiac valve development begins with the endocardial cushions during week 7 of gestation, but formation of mature AV valves (mitral and tricuspid) and semilunar valves (aortic and pulmonic) takes several weeks for completion (de Lange et al., 2004; Lincoln et al., 2004; Kanani et al., 2005; Hinton et al., 2006; Combs and Yutzey, 2009; Dhanantwari et al., 2009; Steding, 2009). As the

Current developments and future prospects for heart valve replacement therapy. *J Biomed Mater Res B Appl Biomater*. 2009;88:290–303.)

endocardial cushions enlarge, they protrude into the lumen of the heart, as shown in Fig. 50.7A–B. Here, subject to constant flow of blood, the protrusions condense and elongate. Endocardial cells overlying the cushions proliferate slowly, and there is programmed cell death (apoptosis) of mesenchymal cells underneath. The valves undergo extensive remodeling of the extracellular matrix; in the case of the semilunar valves, this results in a fibrous layer (primarily collagen) on the arterial side, a spongiosa layer (glycosaminoglycans) in the middle, and an elastic layer (elastin) on the ventricular side (see Fig. 50.7C; Hinton et al., 2006; Shelton and Yutzey, 2007; Combs and Yutzey, 2009). In the case of the semilunar valves, this remodeling of the endocardial cushions continues through the last trimester of pregnancy and into the neonatal period (Aikawa et al., 2006; Hinton et al., 2006).

Recent studies have shed some light on the genetics of cardiac valve disease. For example, Noonan syndrome is characterized by cardiac malformations, including a dysplastic pulmonary valve. Linkage studies of families with Noonan syndrome have identified a candidate gene on chromosome 12, the *PTPN11* gene (Tartaglia et al., 2001). *PTPN11* encodes SHP-2, a nonreceptor protein tyrosine phosphatase important to growth factors, cytokines, and hormones (Tartaglia et al., 2001). A specific role in mediating growth factors during semilunar valve formation had been proposed (Chen et al., 2000), and several human mutations in the gene were recently shown to cause overactivation of SHP-2 (Tartaglia et al., 2002). This suggests a gain-of-function mechanism for the pathogenesis of Noonan syndrome, an interesting distinction from the more familiar concept of the loss of functioning protein causing disease. Likewise, mutations in the Notch1 receptor and various components of the Notch signaling pathway have been associated with the formation of aortic valves and with multiple stages of cardiac development (Garg et al., 2005; High and Epstein, 2008).

Development of the Ventricles and Ventricular Septum

Most of the ventricular septum is muscular and is made up of a protrusion of ventricular myocardium that starts at the apex of the primitive ventricle and extends into the ventricular cavity. The ventricle in the early stage of septation appears as a bilobed structure (Dhanantwari et al., 2009; Steding, 2009); see Fig. 50.8. As the septum extends upward, the separation becomes nearly complete. There is controversy as to how the septum extends so quickly to form a wall between the left and RVs. Part of the answer seems to be rapid proliferation in these myocytes, which retain the ability to divide even as a working myocardium. This property is lost soon after birth, as the mature myocardium is for the most part incapable of proliferation. Small muscular VSDs are very common in newborns. One study screening asymptomatic newborns found an incidence of 53 per 1000 neonates with small muscular VSDs; only 1/10 of these had physical examination signs of their VSD. Nearly 90% of these small defects were closed by 10 months of age (Roguin et al., 1995). These data and other data suggest continued low-level proliferation in human ventricles after birth.

We have said that as the muscular septum grows and extends from the ventricular apex, the separation between the left and RVs becomes nearly complete. There are two important regions of the complete ventricular septum that are completed by endocardial cushions, as discussed earlier. First, the AV endocardial cushions form the posterior septum adjacent to the AV valves. Second, the conal cushions form the conal septum below the great arteries. An important feature of this process is that these regions of septum contain muscle as well as cushion tissue. Muscle cells of the inner curvature of the heart invade the conal cushion and superior AV cushions as they form the septum, in a process termed

• **Fig. 50.8** Atrial and ventricular septation. Human fetal magnetic resonance imaging images in the transverse plane, showing the four chambers of the heart. Orientation as shown by the arrows. (A) Fetus at 7½ weeks' gestation. The atrial septum primum is marked by the arrowhead, with the foramen primum below allowing shunting of blood from the right atrium to the left atrium. Between the ventricles, the muscular intraventricular septum is forming but is not yet complete (asterisk). Scale bar 1.25 mm. (B) Fetus at 8 weeks' gestation. Here the atrial septum primum (asterisk) is fused with the endocardial cushions inferiorly; not seen is the foramen ovale, which allows for continued right to left atrial shunting in the fetus. The arrowhead shows a small residual ventricular septal defect in the inlet (posterior) septum, not yet closed by endocardial cushion tissue. Scale bar 1.5 mm. A, Anterior; L, left; LV, left ventricle; P, posterior; R, right; RA, right atrium; RV, right ventricle. (Modified from Dhanantwari P, Lee E, Krishnan A, et al. Human cardiac development in the first trimester: a high-resolution magnetic resonance imaging and episcopic fluorescence image capture atlas. *Circulation*. 2009;120:343–351.)

myocardialization (Mjaatvedt et al., 1999). These migrating myocytes are nonproliferative, and the entire inner curvature is involved. This produces fibrous continuity between the mitral and aortic valves, completely devoid of muscle. The posterior AV septum and the conal septum, initially nonmuscular, become muscular structures by the process of muscularization. This process is considered by some investigators to complete the looping process. A DORV can be considered a failure of this final stage of looping.

The left and RVs differ not only by their relative positions to one another but also in their basic muscular structure and in their function. Each ventricle can functionally be subdivided into inflow and outflow regions. The RV, as we have discussed, has a conal segment as well and is therefore referred to as a *tripartite ventricle*. In the mature heart the LV is a high-pressure system, connected to systemic pressures, while the RV is connected to the lower-pressure pulmonary circulation. The form of the LV follows its function, with concentric rings of myofibrils that contract with a slight twisting motion, which allows an efficient ejection of blood. In the embryo the myocardium thickens and arranges itself in processes known as *trabeculation* and *compaction*. *Trabeculation* refers to projections of muscular tissue into the lumen of the ventricle, such that the inner surface is no longer smooth walled but is ridged. *Compaction* refers to the alignment of myocytes from random and loosely packed, as they are in the immature myocardium, into bundles of tightly packed and well-coordinated myocytes working as a unit in the mature myocardium (Moorman and Christoffels, 2003).

Development of the Atria and Atrial Septum

Like the ventricular septum, the atrial septum begins as a ridge of muscular tissue, posterior and midline, which expands to divide the right side of the atrium, containing the orifice of the sinus

venous, from the left side of the atrium, containing the orifice of the common pulmonary vein. This structure is known as the *septum primum*, and it grows toward the fusing AV cushions (see Fig. 50.8A). As discussed earlier, the fusing AV cushions will form the inferior portion of the atrial septum (see Fig. 50.8B). However, before the septum primum and the cushions complete atrial septation, small perforations appear, enlarge, and coalesce within the primum septum. The impetus for this is not known. Soon afterward, a new crescent of atrial septum forms on the right-atrial side of the septum primum and begins extending alongside the septum primum. During fetal life, blood flow from the right atrium into the left atrium prevents fusion of these two septa. The septum secundum is significantly more rigid than the septum primum, which flaps open to allow continued right to left flow. After birth and separation from the low-resistance placenta, the left atrial pressure rises significantly, and the atrial shunt reverses. This causes the septum primum to effect a seal against the septum secundum, often leaving a small opening known as the *foramen ovale*. A patent foramen ovale, generally 3 mm or less with a trivial degree of left to right flow, is a normal finding in a newborn and even in many older children and adults. A defect larger than 5 mm may constitute a secundum ASD, a true deficiency in atrial septal tissue in the region of the foramen ovale.

Failure of the cushions to form the most inferior part of the atrial septum results in a primum ASD. Such defects do not close spontaneously and may be associated with other endocardial cushion defects, most commonly a cleft mitral valve. Finally, there is a small contribution to the atrial septum near the junctions of the SVC and the IVC (see later). Defects in this process result in a sinus venosus ASD, and there are superior or inferior types. Such defects again result from deficiency of atrial septal tissue and do not close spontaneously.

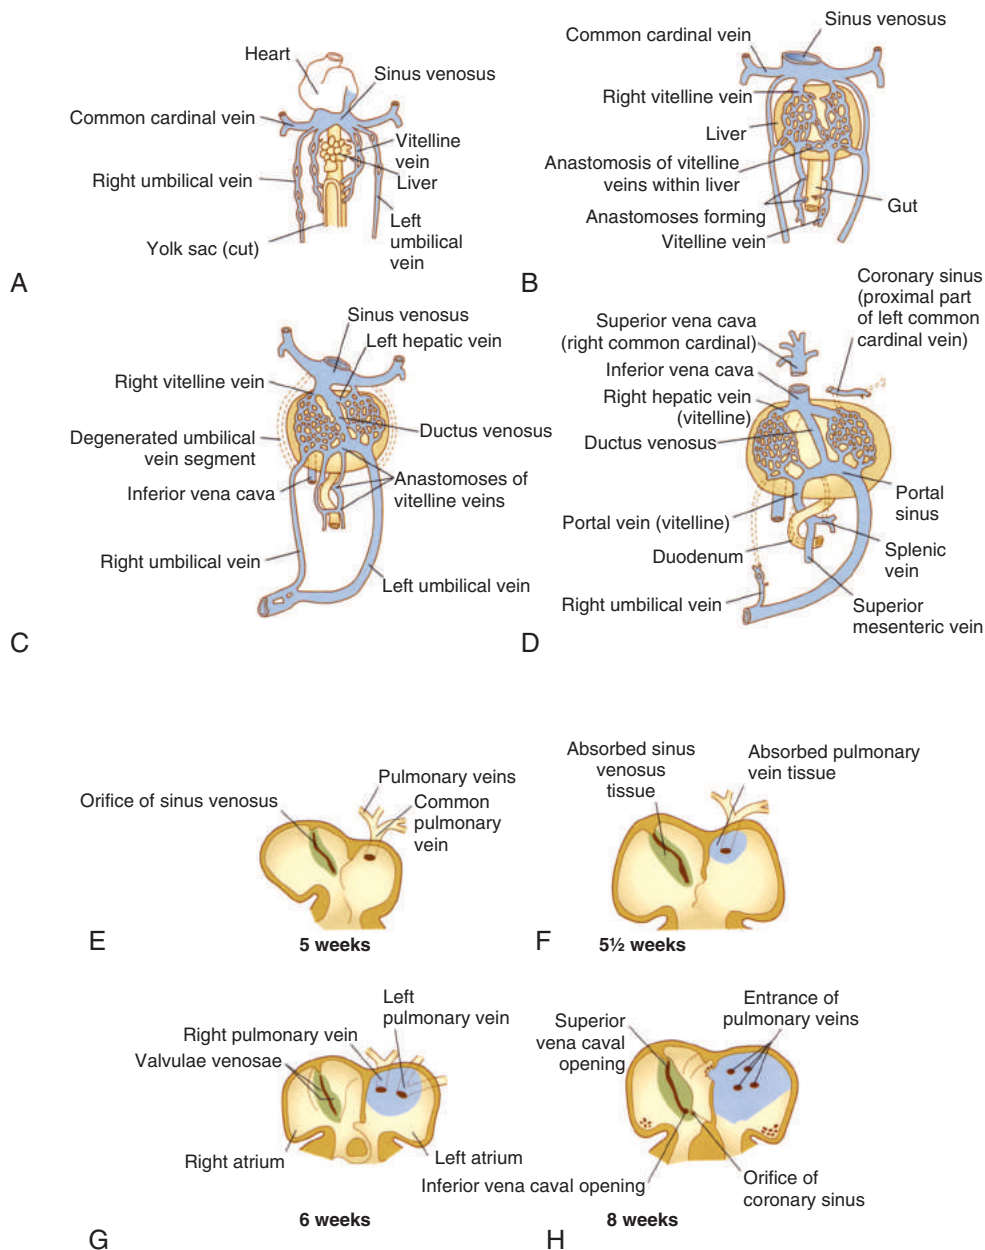

Systemic and Pulmonary Vein Development

The sinus venosus of the primitive heart tube is a symmetric structure and receives three sets of paired (left and right) systemic veins: the vitelline, umbilical, and common cardinal veins (Fig. 50.9A). This is the situation at 4 to 5 weeks' gestation (Minniti et al., 2002).

The vitelline veins return from the yolk sac, a structure that communicates with the primitive gut via the vitelline duct. The duct normally regresses completely, but an occasional remnant can be seen as a Meckel diverticulum (Carlson, 2004). Distally, the vitelline veins regress along with the duct and proximally lose their connection to the sinus venosus proximally by 6 weeks. The midportions of these vessels, however, expand within the liver to contribute to the hepatic and portal veins and contribute a small segment to the IVC (Fig. 50.9B).

The umbilical veins return from the placenta carrying oxygenated blood. These are the first to develop, by 3 weeks' gestation. As the liver develops, the umbilical veins develop connections to the liver venous plexus, and the connection to the sinus venosus involutes. Outside the embryo within the umbilical cord, the left and right umbilical veins fuse into one; thus there is a single umbilical vein in the newborn. Within the embryo the left and right segments remain separate, and the left umbilical vein becomes connected to the right hepatic veins via a new channel that forms, the ductus venosus (Fig. 50.9C, D). This circulation is formed by the 7th week of gestation. Again the umbilical veins are carrying oxygenated blood to the right atrium. This flow is primarily directed toward the atrial septum and therefore primarily through the foramen ovale into the left atrium and systemic circulation.

The cardinal veins carry the venous return from the embryo proper. The left and right common cardinal veins are relatively

• **Fig. 50.9** “Stages of development of the systemic veins (A–D) and pulmonary veins (E–H). (From Carlson BM. *Human Embryology and Developmental Biology*. 4th ed. Philadelphia, PA: Mosby; 2009:452–453.)

short segments that connect to the sinus venosus. On each side, anterior and posterior cardinal veins join to form the common cardinal vein—the anterior cardinal veins carrying the venous return from the upper body and the posterior cardinal veins carrying the venous return from the lower body. The right anterior and right common cardinal veins will form the SVC in the mature circulation. The left common cardinal vein and left segment of the sinus venosus form the coronary sinus, which receives venous return from the coronary system. These structures are pulled rightward as the IVC forms, such that the opening (os) of the coronary sinus ends up in the right atrium once atrial septation is complete. The IVC is more complex and is made up of five segments, coming from urogenital, mesenteric, and hepatic venous channels fusing together to the right of the spine as their leftward paired counterparts involute. As numerous vessels are involved in the making of the IVC, interruption of the IVC can sometimes occur at various segments. This is most often seen in the setting of heterotaxy but can occur in isolation. When the IVC is interrupted, one of two major vessels that connect the lower and upper body venous systems generally enlarges to receive the flow and shunt it into the SVC. These are the rightward azygous vein, which runs from the suprarenal segment of the IVC to the SVC, and the leftward hemiazygos vein, which takes a more tortuous course from the leftward lumbar and renal veins up into the thoracic cavity, where it turns rightward to join the azygous vein. Thus an interrupted IVC generally has either azygous or hemiazygos continuation to the SVC.

The pulmonary veins grow in progressively from the developing lung vasculature, first as a common pulmonary vein from both lungs. This vein fuses into the back of the left atrium (Wessels et al., 2000). As the atrium expands, the common pulmonary vein becomes increasingly absorbed into the back wall, such that first two and then four of its distal branches eventually enter independently into the atrium, two from the left lung and two from the right lung (see Fig. 50.9E–H). The original atrial segment, the heart tube, is not part of the functioning atria in the mature heart, instead relegated to the right and left atrial appendages.

Aortic Arch Development

The primitive heart tube connects to the aortic sac, the precursor to the ascending aorta, and begins pumping to the developing systemic circulation of the embryo as soon as it is formed. The aortic sac connects to paired dorsal aortae posteriorly via an aortic root, which gives rise to a series of arches, the branchial arches (Fig. 50.10A). It is along these arches that the neural crest migrates into the conotruncus and supports development of the arch arteries. Again these are paired structures, and there are six pairs, although not all are patent at the same time. Arches 1–4 carry the blood flow in the 4-week embryo. Arches 1 and 2 mostly regress completely, although parts contribute to some of the arteries of the face. Arch 3 does not persist as an arch but contributes to the formation of the carotid arteries, both left and right. The left limb of arch 4 remains in continuity with the aortic root. Together they make up the true aortic arch and its first branch, the brachiocephalic (innominate) artery. The right limb of arch 4 becomes part of the right subclavian artery, which retains its proximal connection with the brachiocephalic artery (Waldo et al., 1996). This arch remodeling has occurred by 7 weeks' gestation (see Fig. 50.10B). In some cases, either independently or as part of another developmental cardiac defect, the right limb of arch 4 remains patent, and the left forms the left subclavian artery—this forms a right aortic arch with mirror-image branching. Arch 5 is small and never fully

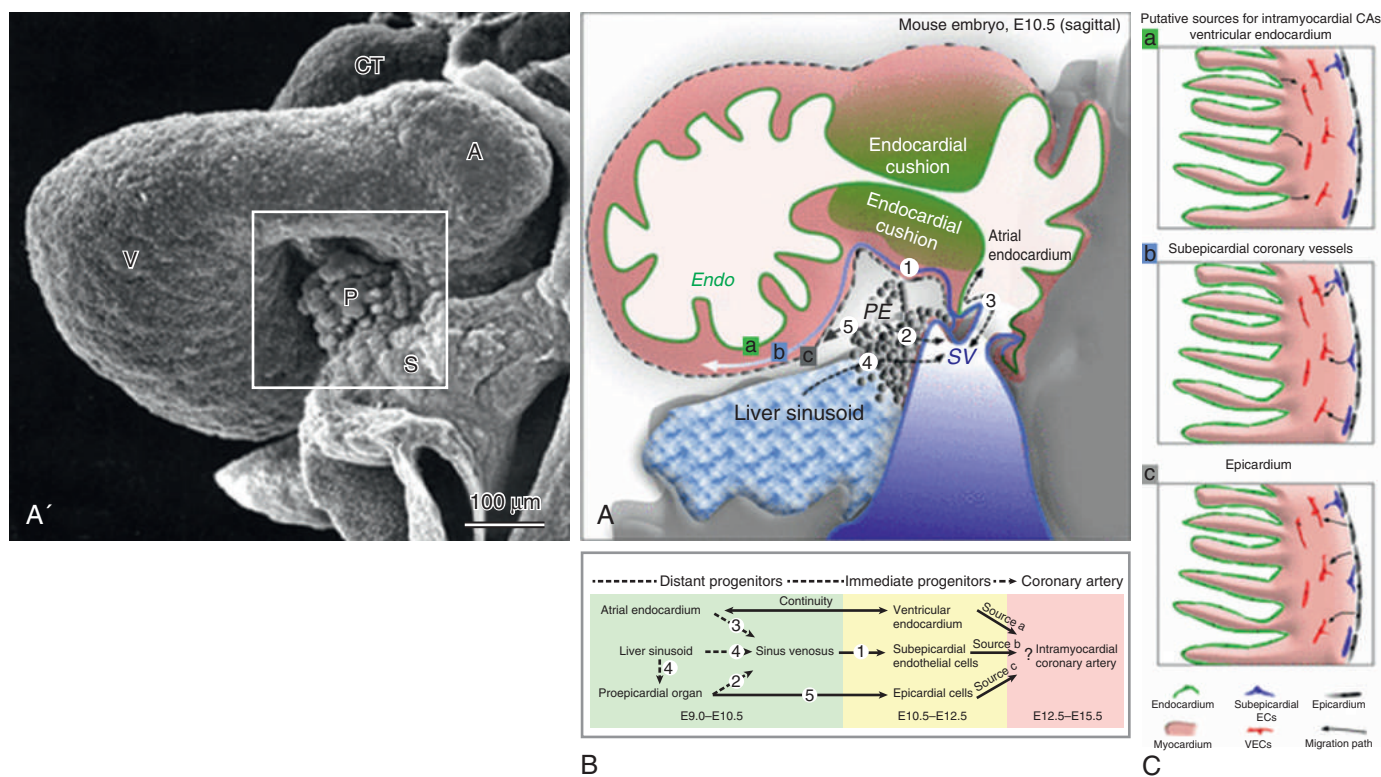

• **Fig. 50.10** (Top) Migration pattern of neural crest cells into pharyngeal arches. (Bottom) Normal aortic arch at term. Most of the pharyngeal arch segments have regressed. The third arch persists in part as the left and right common carotid arteries. The left fourth arch persists as the true aortic arch, while a portion of the right fourth arch makes up the proximal right subclavian artery. The sixth arch persists as the ductus arteriosus (ductal arch). (From Kirby ML. Contribution of neural crest to heart and vessel morphology. In: Harvey R, Rosenthal H, eds. *Heart Development*. New York, NY: Academic Press; 1999:179–193.)

develops. Arch 6 forms with the developing pulmonary artery vasculature and makes up the proximal left and right pulmonary arteries and the ductus arteriosus (Waldo and Kirby, 1993). The ductal arch persists throughout fetal life as another means of right-to-left shunt, allowing blood from the RV to bypass the pulmonary circulation and cross over into the descending aorta.

Coronary Arteries

The coronary arteries were for many years assumed to “sprout” from the ascending aorta and grow over the surface of the heart. This is now known to be incorrect. The coronary arteries form in situ within the myocardium and then connect to a coronary stem that forms within the aorta from peritruncal capillaries (Mikawa and Fischman, 1992; Mikawa and Gourdie, 1996; Tian et al., 2013a; Liu et al., 2015; Tian et al., 2015). The coronary vessels

• **Fig. 50.11** Coronary vessel origins. (A) Scanning electron micrograph showing the developing proepicardial organ (P), sinus venosus (S), atrium (A), ventricle (V), and conotruncus (CT). (A') A mouse embryo at the same stage (embryonic day 10.5) showing the various origins of the coronary plexus, including endocardium (endo; green), proepicardial organ (PE; gray), and sinus venosus (SV; blue). Dashed arrows and numbers denote the migration paths between these cell populations. a, b, and c are the sources within the heart of coronary artery (CA) precursors (a, endocardium; b, subepicardium; c, epicardium). (B) Differentiation path of the various cell types with timing in the mouse embryo; numbers correspond to the migration paths shown in (A). (C) Arrows show migration paths of each cell type into the myocardium (pink), using the same color coding as described above; epicardium arises from the proepicardial organ (black), and subendocardial endothelial cells arise from the sinus venosus (blue). The vascular epithelial cells (VECs) that form the coronary vessels are in red. E, Embryonic day. ([A'] From Hiruma T, Hirakow R. Epicardial formation in embryonic chick heart: computer-aided reconstruction, scanning and transmission electron microscopic studies. *Am J Anat.* 1989;184:129–138. [A–C] From Tian X, Pu, WT, Zhou B. Cellular origin and developmental program of coronary angiogenesis. *Circ Res.* 2015;116:515–530.)

themselves form from several sources. Early in development, bilateral clusters of cells appear near the septum transversum, where the liver bud approaches the heart as the proepicardial organ (Mikawa and Gourdie, 1996; Reese et al., 1999, 2002). This is in close proximity to the sinus venosus, and there appears to be some movement of cells from one population to the other (Tian et al., 2015). The proepicardial organ is a transient structure that spreads out over the surface of the heart as an epithelium, forming the epicardium. Some of the epicardial cells delaminate and migrate into the myocardium, contributing to coronary vasculature, both endothelial cells and arterial smooth muscle, and cardiac fibroblasts. Early studies using lineage tracing methods in chick embryos suggested that most of the coronary arteries, both endothelium and smooth muscle, were formed from this population (Mikawa and Gourdie, 1996; Reese et al., 2002). More recent studies have shown that while this is true for the smooth muscle component of the coronary arteries, the endothelium is more complex in origin. These studies have used detailed transgenic lineage tracing methods in the mouse to show important contributions from the endocardium (Wu et al., 2012) and sinus venosus (Red-Horse et al., 2010; Tian et al., 2013b, 2014). The endocardium-derived

cells invade the myocardium from the inner surface of the heart, migrating toward the epicardial surface and differentiating into coronary artery endothelial cells. The cells from the sinus venosus migrate and expand within the subepicardial space, invading the myocardium as a distinct population from the epicardium. The current understanding of the overall process of coronary endothelial formation is shown in Fig. 50.11. To add to the complexity of cell lineages, this process is not uniform throughout the ventricular myocardium. The coronary vessels within the ventricular septum appear to form differently from the ventricular free wall (Wu et al., 2012; Tian et al., 2015). Regardless of the ultimate origin, the coronary vessels form, grow, and fuse with one another to form a working vasculature. This corresponds to the process of growth and trabeculation of the ventricles. With increasing complexity and thickness of the myocardium, simple diffusion of nutrients from the blood inside the heart is no longer adequate. It is at this point that the coronary artery plexus grows into the aorta just above the aortic valve. Signaling from neural crest, epicardial-derived cells and recently discovered intra-aortic cardiomyocytes appear to play an important guiding role (Erulp et al., 2005; Arima et al., 2012; Chen et al., 2014). Occasionally this process can go awry,

and a coronary artery (usually the left) can join into the pulmonary artery instead of the aorta. This does not damage the fetal myocardium given the low oxygen state of the fetus, with little difference in oxygen tension between the aorta and the pulmonary artery. After birth, however, ischemia sets in rapidly, causing myocardial ischemia and infarction in infancy.

Conduction System

There has also been controversy regarding the origin of the conduction system, and this controversy is largely resolved. The conduction system was suspected to originate from the neural crest by many investigators, migrating in from outside the heart. However, lineage tracing studies show conclusively that the cells of the conduction system actually differentiate *in situ* from myocytes (Waldo et al., 1994; Moorman, et al., 1997; Gourdie et al., 1998; Cheng et al., 1999; Hyer et al., 1999). There is evidence that the developing coronary vasculature is a source of signaling for this transdifferentiation to occur; the conduction system tends to develop alongside coronary vessels (Hyer et al., 1999). Conduction system myocytes express different markers and junctions and have different action potential profiles that allow automaticity (Wessels et al., 1992; Alyonycheva et al., 1997; Moorman et al., 1997; Takebayashi-Suzuki et al., 2001; Hoogaars et al., 2007). Under normal conditions the automaticity of the remaining conduction system is suppressed as the dominant pacemaker of the heart forms, the sinoatrial node. Recently, lineage tracing studies in early chick embryos showed that the sinoatrial node arises from a population of cardiac mesoderm outside the primary and secondary heart fields that coalesce in the heart near the right sinus horn (Bressan et al., 2013). Activation mapping of embryonic chick heart conduction shows that the primitive sinoatrial node begins to function soon after cardiac looping (the site of earliest activation before this being in the left sinus horn) (Bressan et al., 2013). Once active, the sinoatrial node maintains the fastest depolarization and “sets the pace” for the heart rate. This starts at about 1 month of gestation in humans (Phoon, 2001). If the sinoatrial node slows for any reason, other “pacemakers” substitute. Atrial myocytes tend to have the next most rapid automatic rates, followed by the His bundles, then ventricular myocytes. The heart rate in a 5-week fetus is 100 beats per minute (Phoon, 2001). This increases gradually to a rate of 160 beats per minute by 8 weeks’ gestation and then declines slightly during gestation to the 120–130 beats per minute range (Phoon, 2001).

Physiology of Transition

The fetal heart and circulation at the end of 9 weeks are completely formed (Phoon, 2001). As depicted in Fig. 50.12, there are four chambers of the heart, two atria in communication via a patent foramen ovale and two ventricles with complete septation. The left ventricular myocardium is configured differently from the right such that it is capable of working under higher pressure (afterload). There are fully competent AV valves (the mitral and tricuspid) and fully competent semilunar valves (the aortic and pulmonary) that ensure one-way flow through the heart. The venous return from the systemic circulation and the pulmonary circulation enters the right atrium and the left atrium, respectively. The arterial blood is pumped to the body and to the lungs via the great arteries, with a communication between the two via the patent ductus arteriosus (PDA).

Before birth the placenta is a critical component to the fetal circulation, with a single umbilical vein and two umbilical arteries

(see Fig. 50.12A). A full 50% of the fetal blood volume is in the placenta, and 50% is in the body. In the fetus the systemic cardiac output is combined from the left and RVs, with the RV contributing more than the LV to the total output (approximately 65% vs 35%) (Teitel, 1992). This is via the “ductal arch” connecting the main pulmonary artery to the ductus arteriosus and descending aorta. The aortic arch contributes about 60% of its flow to the head and neck vessels, and the rest combines with the ductal flow to reach the lower body and return to the placenta. Return of blood from the placenta (oxygenated) is via the umbilical veins through the ductus venosus to the IVC and right atrium. This blood is under higher pressure than the systemic return from the fetus and is streamed such that at least 25% is directed across the foramen ovale into the left atrium and systemic circulation. The remainder combines the SVC return to cross the tricuspid valve into the RV. Only about 10% of the right-ventricular output goes to the lungs; this small amount of blood returns to the heart via the pulmonary veins into the left atrium, mixes with the oxygenated blood that has crossed the foramen ovale from the right atrium, and passes on to the systemic circulation (Teitel, 1992).

After birth two major factors trigger changes in circulation (see Fig. 50.12B). These are the initiation of respirations with lung expansion and alveolar gas exchange and cutting of the umbilical cord. The result is a drastic reduction in IVC return to the right side of the heart as the placental flow ceases; at the same time there is a drastic increase in capacity of the pulmonary circulation. Thus return to the right atrium decreases and return to the left atrium increases, as does left-atrial pressure. This forces the flap of the foramen ovale up against the atrial wall, reducing the volume and reversing the direction of atrial-level shunting. Thus the fetus has a large patent foramen ovale with right to left flow, which after birth becomes a smaller orifice with left to right flow. Approximately 20% of older children and adults retain a small patent foramen ovale, with a trivial left to right shunt. Also immediately after birth, the increased oxygen tension of the blood that occurs with breathing causes the ductus arteriosus to begin constricting (functional closure). This is a function of smooth muscle within the wall of the PDA and is prostaglandin sensitive. After functional closure the permanent process of anatomic closure, involving apoptosis of smooth muscle and proliferation of connective tissue, converts the PDA into a fibrous ligament (the ligamentum arteriosus). A similar but slower process occurs in the ductus venosus, also causing it to be closed by fibrosis.

Conclusion

We have reviewed heart development, with attention to the morphology, cell biology, genetics, and physiology of the heart as it forms and undergoes remodeling. The field of developmental biology of the heart continues to advance rapidly on all of these fronts. New technologies allow earlier and earlier visualization of the developing human heart, recently as early as 6 weeks’ gestation by cardiac magnetic resonance imaging (Dhanantwari et al., 2009) and 10 to 11 weeks’ gestation by cardiac ultrasonography (Gembruch et al., 2000; Weiner et al., 2002; Cook et al., 2004; Becker and Wegner, 2006; Neuman and Huhta, 2006; Vimpelli et al., 2006; Marques Carvalho et al., 2008; Bennasar et al., 2009). Early ultrasonography has the additional benefit of assessment of cardiac physiology in the embryo, using Doppler technology (Phoon, 2001). Novel genetic techniques allow us to apply what is learned from animal models to humans and to recreate human disease in animal models with greater and greater specificity. The common

• **Fig. 50.12** The fetal circulation at term: (A) before birth and (B) after birth. In (A) the path of oxygenated blood returning from the placenta is shown in *orange*. It mixes with deoxygenated blood returning from the fetal systemic veins shown in *light blue*. There is intracardiac mixing of blood as shown. The upper body receives a higher oxygen content than the lower body, as deoxygenated blood enters the descending aorta via right-to-left flow at the ductus arteriosus. After birth the pulmonary and systemic circulations are completely separated as shown in (B). (From Carlson BM. *Human Embryology and Developmental Biology*. 5th ed. Philadelphia, PA: Mosby; 2014:436, 469.)

goals to be applied to human disease are early recognition of congenital heart malformations, prevention where feasible, and state-of-the-art intervention to allow an abnormal heart to function as normally as possible. Currently such intervention is surgical and cardiac catheterization based and continues to evolve. In the future, gene therapy, cardiac stem cell grafting, and in vitro tissue engineering will likely be added to the therapeutic potentials for patients with congenital heart malformations.

Cardiovascular Compromise in the Newborn

SHAHAB NOORI, TIMUR AZHIBEKOV, BEN LEE, AND ISTVAN SERI

KEY POINTS

- It is difficult to diagnose neonatal shock in its *uncompensated phase* during the immediate transitional period, while it is even more challenging to diagnose it in its *compensated phase* with use of a standard clinical monitoring and clinical approach.
- It is unclear what gestational age- and postnatal age-dependent blood pressure and systemic and organ blood flow values represent hypotension and poor tissue perfusion respectively warranting timely intervention in the neonate. In addition, there is still some uncertainty about which cardiovascular medication or combination of medications to use in neonatal shock with different causes (hypovolemia, myocardial dysfunction, vasoregulatory disturbance, or a combination of two or all of these factors).
- There is very little evidence that management of neonatal hypotension and/or systemic blood flow affects clinically relevant outcomes.
- A thorough understanding of the principles of developmental cardiovascular physiology and the cause, pathophysiology, and clinical presentation of neonatal shock along with the mechanisms of action and the pharmacokinetics and pharmacodynamics of the medications used in the treatment of cardiovascular compromise is essential for the neonatologist to apply the most reasonable approach to treatment of neonatal cardiovascular compromise on the basis of the collective experience and little evidence available in the literature.
- Recent advances in bedside monitoring technologies such as near-infrared spectroscopy, electrical impedance velocimetry, heart rate variability-based early warning systems, and amplitude-integrated electroencephalogram (EEG) along with the use of point-of-care ultrasonography will enable us to systematically and more thoroughly study neonatal circulatory compromise. These developments, along with the introduction and mathematical modeling of genotypic and phenotypic markers that identify subpopulations at higher risk of developing shock before it happens, will undoubtedly lead to earlier diagnosis and evidence-based management of neonatal shock, resulting in improved short-term and long-term outcomes.

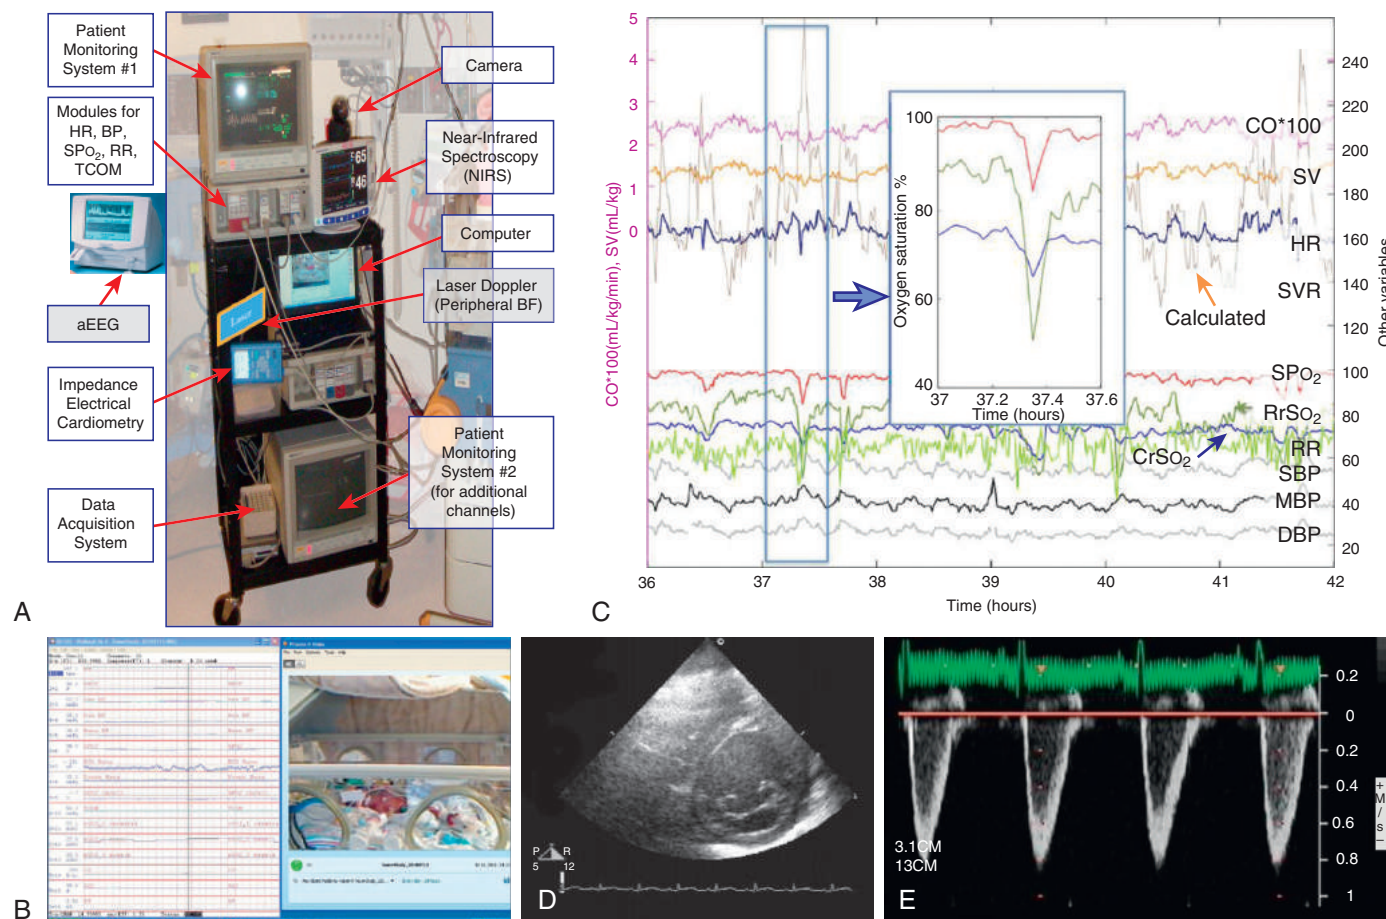

Although the prevalence of hypotension in neonates admitted for intensive care is unclear, up to 50% of very low birth weight (VLBW) neonates present with blood pressure values considered to be low in the immediate transitional period (McLean et al., 2012). However, VLBW neonates account for only approximately 25% of all patients diagnosed with hypotension in neonatal intensive care units. The lack of clear data on

the prevalence of neonatal hypotension is primarily due to the uncertainty about the lower limit of the gestational age- and postnatal age-dependent normal blood pressure range in neonates (Engle, 2012). This is illustrated, among other factors, by the significant differences in the prevalence of the use of vasopressors/inotropes in preterm neonates during the transitional period among different intensive care units across the United States (Al-Aweel et al., 2001; Rios et al., 2014; Wong et al., 2015).

As long as pulmonary gas exchange is adequate, shock is caused by hypovolemia, cardiac failure, vasoregulatory failure, or a combination of these etiologies. Shock has been defined as a “state of cellular energy failure resulting from an inability of tissue oxygen delivery to satisfy tissue oxygen demand” (Singer, 2008). According to this definition, when oxygen delivery is inadequate to meet oxygen demand, the organs start failing and, if corrective measures are not effective, will result in irreversible organ damage and ultimately death. Although oxygen delivery to the organs is dependent on several factors, it is fundamentally driven by both the oxygen content of the blood and the volume of blood flowing to those organs. Because oxygen content is primarily determined by the hemoglobin concentration and oxygen saturation, with less contribution from the dissolved oxygen (see later discussion), it is relatively easily evaluated and monitored in the neonatal intensive care unit. However, reliably assessing systemic and organ blood flow and tissue oxygen delivery and consumption at the bedside is challenging because to provide adequate information on the rapidly changing hemodynamic status of the critically ill neonate, it requires continuous monitoring of key hemodynamic parameters in absolute numbers (Fig. 51.1).

Recent advances in our ability to monitor systemic and organ blood flow and tissue oxygenation as well as vital organ (brain) function at the bedside will likely lead to a better understanding of the complex hemodynamic changes associated with neonatal cardiovascular compromise (Cayabyab et al., 2009; Azhibekov et al., 2015). These advances should lead to the development of treatment modalities more appropriately based on the cause, pathophysiology, and phases of shock, thereby improving clinically relevant outcomes.

At present in clinical practice, tissue perfusion is routinely assessed by the monitoring of heart rate, blood pressure, capillary refill time (CRT), acid-base status, serum lactate levels, and urine output. However, recent Doppler ultrasonography and near-infrared spectroscopy (NIRS) data have highlighted that these parameters

• **Fig. 51.1** Comprehensive, Real-Time Monitoring and Data Acquisition System. Comprehensive monitoring and data acquisition systems allow real-time, continuous and simultaneous assessment of cardiovascular, respiratory, and organ blood flow data, enabling researchers and clinicians to more appropriately evaluate the condition of the patient and follow the changes over time and in response to therapeutic interventions. (A) The comprehensive monitoring and acquisition system developed by the authors' group. The system has the capability to continuously monitor, in absolute values, selected cardiovascular parameters (systolic blood pressure [SBP], diastolic blood pressure [DBP], mean blood pressure [MBP], and heart rate [HR]) and, by the use of electrical impedance velocimetry (Noori et al., 2012c), stroke volume (SV) and cardiac output (CO). Total systemic vascular resistance (SVR) is also continuously calculated by the computer from the pressure and flow data. In addition, with use of near-infrared spectroscopy (NIRS) (Azhibekov et al., 2015), indices of organ blood flow and tissue oxygenation (cerebral regional tissue oxygen saturation [CrSO₂] and renal regional tissue oxygen saturation [RrSO₂]) as well as a number of respiratory parameters (arterial oxygen saturation [SpO₂], respiratory rate [RR], and transcutaneous carbon dioxide tension) are also being obtained. The system includes a motion-activated video camera; a snapshot of the image obtained by the camera is shown (B). The camera allows assessment of patient movements and activities (e.g., seizure) potentially affecting cardiorespiratory functions. In addition, it aids in the postacquisition filtering of motion artifacts. (C) A representative, real-time continuous recording of hemodynamic variables during a period of 6 hours with an oxygen desaturation episode highlighted in the box in a 1100-g, 28 week-gestation preterm neonate. The recording is an example of a preterm infant with a mature response to a hypoxic episode (red line) in which tissue oxygen saturation in the kidney (a nonvital organ; green line) dramatically decreases, while the change in brain (a vital organ; blue line) tissue oxygen saturation is significantly attenuated. Although the system provides a more complete picture of the hemodynamic status, assessment of cardiac function by echocardiography complements the hemodynamic evaluation. Among other factors, echocardiography reveals potential structural heart defects and the presence of shunts between the systemic and pulmonary circulations through a patent ductus arteriosus and/or foramen ovale and can shed light on the underlying cause of circulatory failure. For example, by assessing the movement of the septum and posterior wall of the left ventricle in the short-axis view (D), one can better understand the status of myocardial contractility. In addition, by estimating blood flow velocity (E) and measuring the diameter of the aorta, one can spot-check the validity of the continuous cardiac output data obtained by the electrical impedance velocimetry monitor used in the system. aEEG, Amplitude-integrated electroencephalography; BF, blood flow; TCOM, transcutaneous CO₂ monitoring.

are relatively poor indicators, although at present they are the only routinely available indicators of acute changes in organ blood flow and tissue oxygen delivery in critically ill neonates (Kluckow and Evans, 1996; Lopez et al., 1997; Tysczuk et al., 1998; Kluckow and Evans, 2000a). These observations and the lack of evidence that treatment of neonatal cardiovascular compromise improves outcomes (Seri and Noori, 2005; Barrington et al., 2006) call for a paradigm shift in our thinking about the pathophysiology, diagnosis, and treatment of neonatal shock. This suggests that the assessment of the hemodynamic status in critically ill neonates should include the complex interactions among blood flow and blood pressure as well as tissue oxygen delivery and consumption (Cayabyab et al., 2009; Noori et al., 2012). A comprehensive, real-time hemodynamic monitoring and data acquisition system has been developed recently (Soleymani et al., 2012; Azhibekov et al., 2014, 2015), although its use is limited to clinical research (Fig. 51.2).

Principles of Developmental Cardiovascular Physiology and Pathophysiology, Phases, and Causes of Neonatal Shock

Principles of Oxygen Delivery

Oxygen is essential for mitochondrial respiration but is not stored in the body. Thus interruption of oxygen supply to cells can result in irreversible damage (sometimes within minutes), particularly in vital organs such as the brain and myocardium.

The primary function of the cardiorespiratory system is to provide adequate oxygen delivery to *tissues*. Accordingly, shock is defined as inadequate systemic tissue oxygen delivery (see earlier). Oxygen delivery can be expressed as

$$\text{DO}_2 = \text{Cardiac Output} \times \text{Arterial Oxygen Content (CaO}_2\text{)},$$

where

$$\text{Cardiac Output} = \text{Heart Rate} \times \text{Stroke Volume}$$

and

$$\begin{aligned} \text{CaO}_2 = & (1.34 \times \text{Hemoglobin Concentration} \\ & \times \text{Arterial Oxygen Saturation [SaO}_2\text{]}) \\ & + (0.003 \times \text{Arterial Partial Pressure of Oxygen [PaO}_2\text{]}). \end{aligned}$$

Stroke volume is the result of complex interplay among preload, afterload, and contractility (Fig. 51.3), all three of which are, at present, impossible to monitor reliably and continuously at the bedside. Although these parameters are more fully described later, in brief, preload is the end-diastolic volume of the ventricle (a three-dimensional reflection of precontractile myocardial cell fiber length), and, up to a point, the greater the preload, the larger the stroke volume (the Frank–Starling relationship). Afterload is the force the ventricle must generate against the systemic or pulmonary vascular resistance. As long as appropriate perfusion pressure is ensured, the lower the afterload, the greater the cardiac output. Contractility (the intrinsic ability to generate force per unit time) may be assessed noninvasively but not continuously by echocardiogram. Considering at present most of the measures of cardiac contractility are both preload and afterload dependent, contractility is not truly an independent variable. In addition, cardiac output in neonates is considered more heart rate–dependent than contractility-dependent because the ability of neonates to augment

their stroke volume is limited when compared with the ability of children or adults.

From this simple model it is easily appreciated that if there is an acute decline in CaO_2 , caused by a decrease in either the hemoglobin concentration or SaO_2 or both, the cardiac output will increase in response to maintain DO_2 . On the other hand, because neither hemoglobin concentration nor SaO_2 can be physiologically increased rapidly, there is no acute compensation for a low cardiac output due to decreases in myocardial contractility and/or preload.

The purpose of oxygen delivery is to provide oxygen for oxygen consumption (VO_2), which can be expressed as

$$\text{VO}_2 = \text{Cardiac Output} \times (\text{CaO}_2 - \text{CvO}_2),$$

where CvO_2 is the mixed venous oxygen content.

This relationship is based on the Fick principle, from which, knowing the flow rate and the arterial–venous content difference of a trace element (in this case oxygen), one can calculate the rate of uptake or removal of the tracer.

Normally DO_2 and VO_2 are well matched with O_2 extraction, being approximately 25%. Accordingly, if SaO_2 is 100%, SvO_2 would be expected to be 75%. If cardiac output falls, VO_2 may be maintained constant by capillary bed vasodilation and recruitment and/or by increased O_2 extraction by the tissues. Increased O_2 extraction is manifested as lower CvO_2 and therefore a greater CaO_2 and CvO_2 difference. The relationship between DO_2 and VO_2 may be graphically displayed as in Fig. 51.4. Once oxygen extraction is maximal, at the critical DO_2 threshold, anaerobic metabolism ensues, resulting in lactic acidosis. If not reversed, the oxygen debt accumulates, and organ failure and death will ensue. In general, during aerobic metabolism 38 mol adenosine triphosphate (ATP) is produced per mole of glucose, whereas during anaerobic metabolic conditions, 2 mol ATP and 2 mol lactate are produced per mole of glucose.

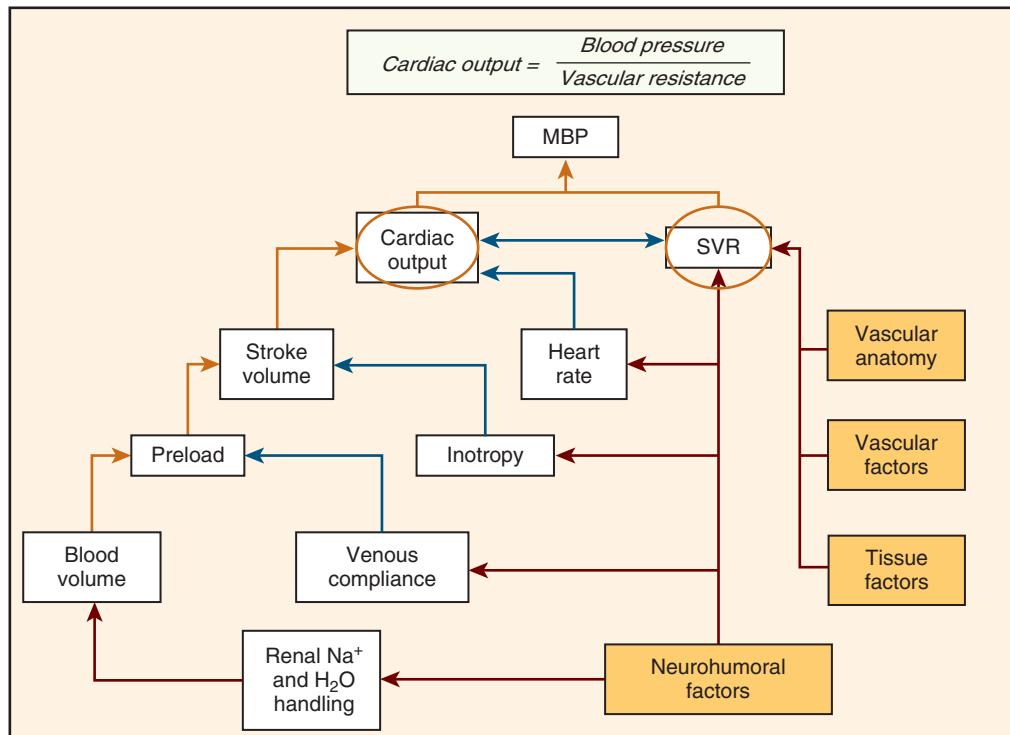

Before the stage of delivery-dependent VO_2 is reached, SvO_2 can be used as a proxy for DO_2 . Assuming VO_2 , hemoglobin concentration, and SaO_2 are constant over a short period, a decline in SvO_2 represents a decrease in cardiac output. This relationship is clinically important, as SvO_2 can be measured intermittently via a venous catheter, ideally placed in the pulmonary artery in a patient without intracardiac shunts so as to obtain a true mixed venous sample. Central venous oxygen saturation (ScvO_2) may also be used as a proxy for DO_2 , measured via a venous catheter with its tip at the superior vena cava (SVC)—right atrial junction. It is of note that the location of the catheter tip is critical; if the tip is located lower in the right atrium, it will sample more desaturated blood streaming from the coronary sinus and/or hepatic veins. However, for several reasons, measurement of ScvO_2 is not done routinely in neonates in neonatal intensive care units except for in some neonates with congenital heart disease in the postoperative period following surgical correction of the underlying cardiac condition.

In general, these principles are valuable guides to understanding and managing global DO_2 and VO_2 , but they do not readily assist with the assessment of individual organ DO_2 . Furthermore, the limitations of measuring VO_2 , DO_2 , and even just ScvO_2 are often daunting. However, advances in noninvasive regional tissue oxygen saturation (rSO_2) monitoring via NIRS have increasingly allowed such assessments in different tissues, including the brain, kidneys, intestine, and muscle (see later discussion).

Finally, there is a class of neonates where calculations using the Fick principle can be critical in directing therapy. Newborns with

• **Fig. 51.2** Real-time Recording of 12 Hemodynamic Parameters in a Neonate. Real-time, 60-minute recording of 12 hemodynamic parameters in a 1-day-old, 3000-g, 36-week late preterm neonate receiving dopamine at 2 $\mu\text{g}/\text{kg}$ per minute. Recording was blinded to the clinical team. The patient's blood pressure decreased (left red arrow), and a 10 mL/kg physiologic saline bolus was started at the 10-minute mark of the recording to be administered in 15 minutes. No changes occurred in systolic blood pressure (SBP), mean blood pressure (MBP), diastolic blood pressure (DBP), cerebral regional tissue oxygen saturation (CrSO_2), renal regional tissue oxygen saturation (RrSO_2), and muscle regional tissue oxygen saturation (MrSO_2) measured by near-infrared spectroscopy, arterial oxygen saturation (SPO_2), transcutaneous CO_2 tension (TCOM), and respiratory rate (RR). However, stroke volume (SV; monitored by impedance electrical cardiometry) increased and heart rate (HR) decreased probably because of improved preloading conditions during the volume bolus. As the magnitude of the increase in SV was greater than the decrease in HR, cardiac output (CO) also increased ($\text{CO} = \text{SV} \times \text{HR}$). There is great variability in the trend of CO and SV values shown that may be attributed to beat-to-beat variations in SV, HR variability, or other physiologic effects and/or the limitations of the technology. Considering MBP did not change, calculated systemic vascular resistance (cSVR) also decreased (systemic vascular resistance = MBP/CO). In addition, considering CrSO_2 , RrSO_2 , and MrSO_2 did not change while SPO_2 also remained stable, it is likely that cerebral, renal and muscle blood flow also remained basically unchanged during the volume bolus. The effect on cardiac output lasted for only 10 minutes after the discontinuation of the volume bolus, and thereafter all but one of the monitored hemodynamic parameters remained unchanged. The only exception was the increase in SPB, MBP, and DBP occurring approximately 3 to 5 minutes after the volume bolus was completed (right red arrow). The change in blood pressure appears to be unrelated to the changes in the other hemodynamic parameters or the administration of the volume bolus. However, on return of the clinical team 30 minutes after the initiation of the volume bolus, and without knowledge of the changes in the hemodynamic parameters, it must have been tempting for the clinical team to speculate that the volume administration "worked" as the blood pressure returned to the previous levels. The shaded area highlights the period of hemodynamic changes during and 10 minutes after the volume bolus. The left y-axis depicts SV (mL) and CO (100 mL/minute) and the right y-axis shows the values for SPO_2 (%), CrSO_2 (%), RrSO_2 (%), MrSO_2 (%), HR (1/minute), RR (1/minute), TCOM (mmHg), SPB (mmHg), MBP (mmHg) and DBP (mmHg), and cSVR (millimeter of mercury-minutes per liter). Min, Minute; mL, milliliter. (Courtesy Soleymani S, Borzage M, Noori S, Seri I. Neonatal hemodynamics: monitoring, data acquisition and analysis. *Expert Rev Med Devices*. 2012;9:501–511.)

• **Fig. 51.3** Factors Regulating Cardiac Output, Blood Pressure, and Systemic Vascular Resistance. From a physiologic standpoint, systemic vascular resistance (SVR) and cardiac output are the regulated (independent) variables and mean blood pressure (MBP) is the dependent variable. (Modified from Klabunde RE. Factors Regulating Arterial Blood Pressure; 2016. <http://www.cvphysiology.com/Blood%20Pressure/BP022>.)

• **Fig. 51.4** Relationship Between Oxygen Consumption and Delivery. In the normal range of oxygen delivery, oxygen consumption is unaffected by changes in the rate of delivery of oxygen to the tissues. As oxygen delivery decreases below the normal range, tissue oxygen consumption remains in the normal range for a while because of activation of local compensatory mechanisms such as capillary recruitment and increased oxygen extraction. However, when oxygen delivery decreases to the "critical" point, compensatory mechanisms can no longer satisfy tissue oxygen demand, and anaerobic metabolism commences, resulting in significantly decreased ATP and increased lactate production.

congenital heart disease and intracardiac shunts may have perturbations in the usual pulmonary-to-systemic blood flow ratio (Q_p/Q_s). Normally, of course, in patients with the two circulations in series and no shunts, $Q_p/Q_s = 1$. By comparing the oxygen used by the body with the oxygen taken up by the lung, one can estimate Q_p/Q_s :

$$Q_s = VO_2 / (CaO_2 - CvO_2)$$

and

$$Q_p = O_2 \text{ Uptake} / (C_{pv}O_2 - C_{pa}O_2),$$

where pv and pa represent pulmonary vein and pulmonary artery, respectively.

After substitution and elimination of common terms, we have

$$Q_p/Q_s = (SaO_2 - SvO_2) / (SpvO_2 - SpaO_2).$$

This formula requires two assumptions, unless saturation values are determined directly, as done in the cardiac catheterization laboratory: first, $SpvO_2$ is 95% to 100%, and second, SvO_2 measured through a central venous line reflects a mixed venous sample. A Q_p/Q_s ratio of less than 1 would suggest the presence of a right-to-left shunt and, typically, decreased pulmonary circulation, both of which result in less oxygenated blood entering the systemic circulation with resultant cyanosis. A Q_p/Q_s ratio greater than 1, in turn, would suggest left-to-right shunting, with resultant pulmonary overcirculation. Of note is that changes in Q_p/Q_s in either direction will affect oxygen content and/or oxygen delivery to the organs.

The value of this calculation can be illustrated with the following example. A newborn with hypoplastic left-sided heart syndrome

is found to have SaO_2 of 95% and SvO_2 of 80%. Using the formula just given, assuming SpvO_2 of 100% and recognizing that SaO_2 and SpaO_2 are the same in this patient, we arrive at a Qp/Qs ratio of 3:1. If systemic blood flow is to be preserved, the single right ventricle will need to sustain a fourfold increase in cardiac output, whereas the significant pulmonary overcirculation will lead to the development of congestive heart failure. The inability of the right ventricle to sustain such an increase in cardiac output will then lead to inadequate systemic blood flow, resulting in shock. Importantly, both conditions can be present at the same time. However, if SaO_2 is maintained within the target range of 75% to 85% in these patients, the Qp/Qs ratio will shift closer to 1:1, providing a simplistic rationale for the use of such an SaO_2 target range. However, in patients with hypoplastic left-sided heart syndrome, the effects of shunting on blood oxygen content and/or delivery are far more complex as systemic oxygen availability is determined, along with other factors, by the relationship among SpvO_2 , SaO_2 , SvO_2 , and cardiac output (Barnea et al., 1994). Accordingly, in addition to a targeted SaO_2 range, management of these patients must be guided by the difference in systemic arterial and venous oxygen saturations and other indicators of tissue perfusion (see also Chapter 55).

Developmental Regulation of Cardiac Output and Its Determinants

Cardiac output is the product of stroke volume and heart rate and is determined by the amount of blood returning to the heart (preload), the strength of myocardial contractility, and the load against which the heart must pump (afterload). Unlike preload, afterload is in general more difficult to conceptualize, and therefore *afterload* is often used interchangeably with the simpler but less accurate term *vascular resistance*. However, although afterload is altered by changes in vascular resistance, other factors also determine its magnitude. Afterload is the load or force the heart faces during contraction and is affected by the impedance of the central vasculature, the resistance of the peripheral vascular beds, the ventricular mass, blood pressure, and the inertia of the blood. In addition, it is affected by myocardial contractility and preload. If myocardial function is intact, cardiac output depends solely on preload and afterload according to the relationships described by the Starling curve.

Therefore low cardiac output and thus low systemic blood flow can result from various combinations of abnormalities of the three determinants of cardiac output: low cardiac preload, poor myocardial contractility, and high cardiac afterload. In addition, extremes of these variables in the opposite direction (i.e., high cardiac preload, increased myocardial contractility, and low cardiac afterload) can contribute to cardiovascular insufficiency, albeit not as commonly. This is because these three variables, as well as heart rate, affect one another. For example, in an infant of a diabetic mother with hypertrophied cardiomyopathy, increased contractility and low afterload can further compromise systemic flow by reducing preload and worsening left ventricular outflow tract obstruction.

Preload

Decreases in preload lead to diminished stroke volume and cardiac output and are most often caused by low effective circulating blood volume. This can be due to loss of circulating blood volume following hemorrhage (absolute hypovolemia), or the circulating volume may be inadequate for the vascular space as in vasodilatory shock or as a side effect of administration of lusitropes (relative

hypovolemia). Because approximately 75% of the circulating blood volume is on the venous side of the circulation at any given time, the increases in venous capacitance caused by venodilation significantly contribute to relative hypovolemia under these circumstances. Because preload is also augmented by the negative intrathoracic pressure generated at each spontaneous inspiration, the positive intrathoracic pressure associated with positive pressure mechanical ventilation reduces venous return and hence preload and cardiac output (Henning, 1986; Biondi et al., 1988).

Contractility

The strength of myocardial contractility depends on the filling volume and pressure and the maturity (Friedman, 1972) and integrity of the myocardium. Thus decreases in preload (hypovolemia, cardiac arrhythmia), prematurity (especially extreme immaturity), hypoxic insults, and infectious (viral or bacterial) agents (Walther et al., 1985a) all negatively affect the ability of the myocardium to contract, with resultant decreases in cardiac output.

Afterload

If cardiac afterload is too high, the ability of the myocardium to contract and pump may become compromised, and cardiac output may fall (Roze et al., 1993; Osborn et al., 2002). Such increases in afterload are associated with enhanced endogenous catecholamine release during the period of immediate postnatal adaptation along with loss of the low-resistance placental circulation. Similar increases in afterload are seen in hypovolemia, hypothermia, or when inappropriately high doses of vasopressors/inotropes are being administered to a patient with intact cardiovascular adrenoceptor responsiveness (Seri, 2006). High afterload can affect either ventricle, and if the output of one of the ventricles is reduced, this will affect the function of the other ventricle, especially when the fetal channels are closed. For instance, if the right ventricular output is low because of high pulmonary vascular resistance, the amount of blood traversing the lungs to the left ventricle will be reduced, leading to low systemic blood flow, with blood pooling in the systemic venous system.

Changes in Preload, Contractility, and Afterload During Transition

With delivery and the separation of the placenta, the fetal circulation begins its transition to the mature (adult-type) circulation in which the systemic and pulmonary circuits are in series and, with the closure of the fetal shunts between the two circulations, the right and left cardiac outputs are equal. However, some component of the normal transition (e.g., removal of placental circulation) is rather abrupt, whereas other components (cessation of flow through the ductus arteriosus and foramen ovale) are more gradual (Kiserud and Acharya, 2004). With the initiation of breathing resulting in lung expansion and the separation of placenta, the pulmonary vascular resistance drops precipitously and systemic vascular resistance increases, respectively. The resultant increase in the left ventricular afterload could lead to a decrease in myocardial contractility, which in selected populations of vulnerable preterm infants may result in decreased cardiac output. In addition, the aforementioned changes in the pulmonary and systemic vascular resistance lead to an evolution in ductal flow pattern from a purely right-to-left to bidirectional and, eventually, purely left-to-right ductal flow. In healthy term infants, left ventricular stroke volume and output increase in the first few minutes after birth. This change coincides with increasing net left-to-right ductal shunting (Noori et al.,

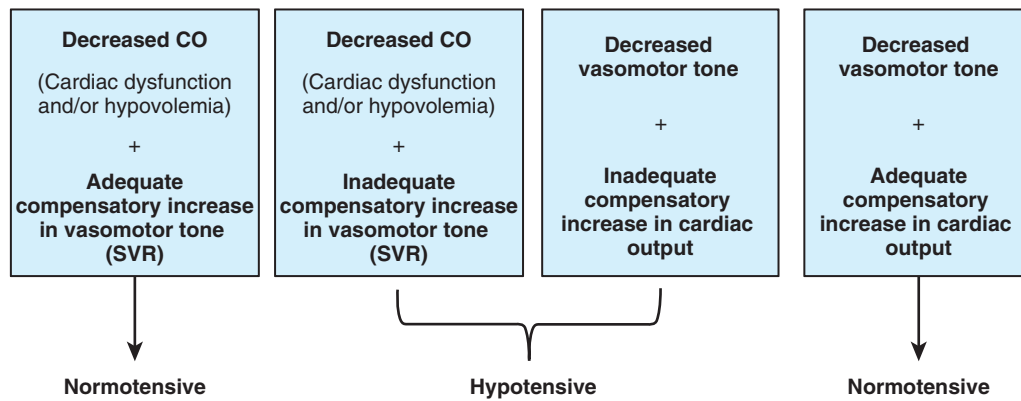

• **Fig. 51.5** Impact of Left-to-Right Shunting Across the Patent Ductus Arteriosus and Patent Foramen Ovale on Left Ventricular Output and Right Ventricular Output Measurements. Effect of left-to-right shunting across the ductus arteriosus and patent foramen ovale on left ventricular output and right ventricular output. Under these circumstances, left ventricular output represents the sum of total pulmonary venous return and ductal blood flow, whereas right ventricular output measures the sum of systemic venous return and left-to-right shunting across the patent foramen ovale. LA, Left atrium; LV, left ventricle/left ventricular; RA, right atrium; RV, right ventricle/right ventricular; SBF, systemic blood flow. (Reproduced with permission from Kluckow M, Evans N. Low systemic blood flow in the preterm infant. *Semin Neonatol.* 2001;6:75-84.)

2012b). The increase in left ventricular preload from ductal shunting likely explains the increase in left ventricular output, and the increase in left ventricular output may offset the potential impact of the left-to-right ductal shunt on the systemic circulation. Therefore, there is usually no evidence of circulatory compromise in the healthy neonate. Subsequently, the ductus arteriosus constricts and then closes in the vast majority of term neonates within 24 to 48 hours. Therefore in the healthy term neonate, the rapidly constricting ductus arteriosus prevents the development of hemodynamically significant left-to-right shunting across the ductus. However, the transition to adult-type circulation is prolonged in preterm infants and especially in extremely preterm infants and can result in circulatory compromise (Kluckow and Evans, 2000b). In 50% to 70% of VLBW neonates, the ductus arteriosus remains open (Reller et al., 1993; Clyman and Noori, 2012), and, as the right-sided pressures fall, blood will shunt left to right from the systemic circulation back into the pulmonary circulation. In most VLBW neonates, pulmonary vascular resistance initially decreases relatively rapidly for physiologic and nonphysiologic reasons (Clyman and Noori, 2012). The physiologic mechanisms most important in the postnatal decrease of pulmonary vascular resistance include the mechanical effects of initiation of breathing on pulmonary vascular resistance and the increased postnatal oxygenation-associated direct, paracrine, and endocrine vasodilation (Faro et al., 2007). Iatrogenic causes include surfactant administration and the inappropriate targeting of higher arterial oxygen saturations (Kluckow and Evans, 2000b; Clyman and Noori, 2012). With the left-to-right ductal shunting, pulmonary overcirculation develops, and left ventricular output, the gold standard of bedside assessment of systemic perfusion, cannot be used as a measure of systemic perfusion (Fig. 51.5; Kluckow and Seri, 2012). Under

these circumstances, left ventricular output measures systemic perfusion and ductal blood flow. In earlier studies investigating the posttransitional changes in systemic perfusion and/or the effects of vasoactive agents on cardiovascular function, this fact was often not acknowledged (Roze et al., 1993; Lundstrom et al., 2000). Therefore the conclusions drawn from some of these studies (Roze et al., 1993) need to be reevaluated. More recent studies have acknowledged this hemodynamic paradigm and used right ventricular output to assess systemic perfusion in the VLBW neonate during the transitional period (Kluckow and Evans, 2000a; West et al., 2006; Abdel-Hady et al., 2008; Bouissou et al., 2008). However, right ventricular output represents systemic perfusion only as long as left-to-right shunting across the foramen ovale does not become significant. In many preterm neonates, however, as left-to-right shunting across a nonconstricting patent ductus arteriosus (PDA) increases during the first 12 to 36 hours, left atrial volume and pressure increase, often leading to the development of a significant left-to-right shunt across the foramen ovale (Evans and Iyer, 1994). The left-to-right shunt through the patent foramen ovale will then render the use of right ventricular output as a measure of systemic blood flow inaccurate, because right ventricular output now represents systemic inflow and patent foramen ovale flow (Kluckow and Seri, 2012). This hemodynamic scenario results in the lack of an acceptable conventional measure of systemic blood flow in these neonates. To circumvent this problem, SVC flow has been used as a measure of upper body blood flow in preterm neonates with the fetal channels open (Kluckow and Evans, 2000a; Kluckow, 2005). The use of SVC flow has provided novel insights into the mechanisms of transitional hemodynamics, such as the observation that intraventricular hemorrhage develops in many VLBW neonates as systemic blood flow increases, resulting in reperfusion of the brain (Kluckow and Evans, 2000c) (see later discussion). However, the vulnerability of SVC flow measurements to error and the technical difficulties associated with their use as a surrogate measure of systemic blood flow have forced these measurements to remain primarily as a research rather than a clinical tool (Evans, 2012; Ficial et al., 2013).

Developmental Regulation of Systemic Blood Pressure

Systemic blood pressure is the product of systemic blood flow and systemic vascular resistance. There is an association between low blood pressure and central nervous system injury in the preterm neonate (Miall-Allen et al., 1987; Bada et al., 1990; Goldstein et al., 1995; Watkins et al., 1999). Yet, blood pressure correlates only weakly with blood flow in this patient population during the period of immediate postnatal adaptation when the fetal channels are open (Kluckow and Evans, 2000a). Thus in preterm infants during the first postnatal day, blood pressure may be low because resistance (vasomotor tone) is low even in the presence of normal or high blood flow (Fig. 51.6). Alternatively, blood pressure may be normal or high because resistance is high in the presence of normal or low blood flow (Evans and Kluckow, 1996). The uncertainty surrounding the nature of the relationship between blood pressure and systemic blood flow during the transitional period results from our inability to appropriately define the normal blood pressure range (Engle, 2012) and systemic blood flow (see earlier) and to characterize the developmental regulation of organ blood flow and vital organ assignment (see later discussion) in the preterm neonate.

• **Fig. 51.6** Pathophysiology of Neonatal Cardiovascular Compromise in Primary Myocardial Dysfunction and Primary Abnormal Vascular Tone Regulation With or Without Compensation by the Unaffected Other Variable. Illustration of why blood pressure can remain in the “normal” range when there is an appropriate compensatory increase in either vasomotor tone or cardiac output (CO). In the hypotensive scenarios, the compensatory mechanisms have been exhausted. SVR, Systemic vascular resistance. (Courtesy Wu TW, Noori S, Seri I. Neonatal hypotension. Developmental Regulation of Organ Blood Flow and Its Autoregulation and Vital Organ Assignment

Cerebral Blood Flow Autoregulation

Even very immature preterm neonates autoregulate their cerebral blood flow (CBF) (Seri et al., 1998; Tyszczuk et al., 1998; Tsuji et al., 2000). However, the autoregulatory blood pressure range in this patient population is believed to be narrow, and thus “normal” blood pressure is very close to the lower elbow of the autoregulatory curve (Greisen, 2005, 2012). Organ blood flow autoregulation is impaired in preterm neonates who are sicker and/or more immature (Tsuji et al., 2000; Wong et al., 2008; McLean et al., 2012). In these patients, changes in blood pressure are mirrored by changes in CBF with a high coherence, and these babies are at higher risk of cerebral injury (Pryds et al., 1989; Tsuji et al., 2000; Wong et al., 2008; O’Leary et al., 2009). Factors that impair CBF and other organ blood flow autoregulation include birth asphyxia, acidosis, infection, hypoglycemia, tissue hypoxia and ischemia, and sudden alterations in arterial carbon dioxide tension (PaCO₂) (Greisen, 2012). It is of clinical importance that the CO₂–CBF reactivity is more robust than the blood pressure–CBF reactivity, as a 1-mmHg change in PaCO₂ results in an approximately 4% change in CBF, whereas a 1-mmHg change in blood pressure is associated with an approximately 1% to 2% change in CBF only (Müller et al., 2002; Greisen, 2005). The impairment of CBF autoregulation in the preterm neonate during the immediate postnatal period has been proposed to contribute to cerebral injury with loss of vascular reactivity to both blood pressure and CO₂ (Pryds et al., 1989; O’Leary et al., 2009). However, the finding that impaired autoregulation may also be a consequence of a preceding ischemic insult (Greisen, 2012) makes clarification of this question particularly difficult.

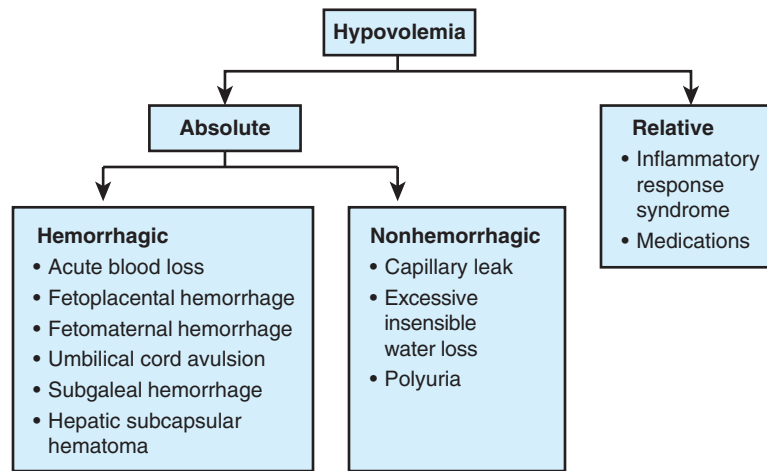

Vital Organ Assignment

The vessels of the vital organs respond to decreased perfusion pressure and/or oxygen delivery with vasodilation (i.e., high-priority vascular beds), whereas the vessels of the nonvital organs, with low-priority vascular beds, vasoconstrict. Several lines of

evidence in human neonates and developing animals suggest that the assignment of the forebrain circulation to a high-priority vascular bed may not be complete at birth (Hernandez et al., 1982; Ashwal et al., 1984; Victor et al., 2006a). For instance, the vessels of the forebrain of dog pups vasoconstrict like those of a nonvital organ, whereas the vessels of the hindbrain vasodilate in response to hypoxia (Hernandez et al., 1982). The finding that CBF autoregulation also appears in the brainstem first and in the forebrain only later in gestation (Ashwal et al., 1984) supports the notion that there are developmentally regulated differences in the timing of the blood flow autoregulatory functions and vital organ assignment characteristics between the forebrain and the hindbrain. The cellular mechanisms responsible for the assignment of vital and nonvital organ status from a blood flow regulatory standpoint are poorly understood. From these findings it is tempting to speculate that the diminished capacity of the forebrain vessels to vasodilate in the very preterm neonate during the complex process of cardiovascular transition after delivery may contribute to hypoperfusion of the forebrain. These neonates may have blood pressures in the perceived normal range while being in the compensated phase of shock. Because this early phase of shock is difficult to recognize immediately after delivery, and because the forebrain is a nonvital organ in very preterm neonates immediately after delivery (Noori et al., 2009), forebrain hypoperfusion can go unnoticed. Similarly, the subsequent evolution to the reperfusion phase as a result of eventual adaptation of the cardiovascular system to the extrauterine environment may not be detected clinically. The proposed nonvital organ assignment–associated hypoperfusion–reperfusion cycle might then contribute to cerebral injury in the very preterm neonate (Noori et al., 2009, 2014a; see later).

Developmental Regulation of Cerebral Oxygen Demand–Delivery Coupling

Very little is known about the regulation of oxygen demand–oxygen delivery coupling in neonates, especially in the transitional period. Yet, several lines of evidence indicate that the very preterm neonate is unable to couple cerebral oxygen demand with cerebral blood flow and instead increases oxygen extraction when oxygen demand is increased (Victor et al., 2006a, 2006b). This phenomenon may

• **Fig. 51.7** Causes of Hypovolemia in Neonates. Etiological factors responsible for absolute (hemorrhagic and nonhemorrhagic) and relative hypovolemia.

be linked to the developmental delay in the vital organ assignment of the forebrain immediately after delivery (see earlier discussion).

Phases of Shock

From a pathophysiologic standpoint, three phases of shock depicting advancing severity have been identified (Zaritsky and Chernow, 1984; McLean et al., 2012).

In the “compensated phase,” complex neuroendocrine and autonomic compensatory mechanisms maintain perfusion and oxygen delivery in the normal range to the vital organs (brain, heart, and adrenal glands) at the expense of decreased perfusion to the remaining organs (nonvital organs). This is achieved by vasodilation and vasoconstriction of the vessels to vital and nonvital organs respectively in response to a fall in perfusion pressure and/or oxygen delivery (Sheldon et al., 1979; Iwamoto, 1993). Blood pressure is maintained within the normal range, and heart rate increases. As perfusion of nonvital organs is decreased because of the compensatory vasoconstriction of their vascular beds, there are often clinical signs of compromised nonvital organ function, such as decreased urine output. In addition, signs of poor peripheral perfusion can often be detected, such as cold extremities and prolonged CRT.

If adequate treatment is not commenced, compensatory neuroendocrine and autonomic mechanisms begin to be exhausted, and hypotension develops as the shock enters its “uncompensated phase.” Systemic perfusion (cardiac output) will decrease, perfusion of all organs including the vital organs becomes compromised, and lactic acidosis develops (Zaritsky and Chernow, 1984).

If treatment is ineffective in the uncompensated phase of shock, multiorgan failure develops, and shock may enter its “irreversible phase,” where permanent damage to the various organ systems occurs, and further interventions will be ineffective in reversing the patient’s condition.

Pathogenesis of Neonatal Shock

Etiologic Factors

The etiologic factors leading to the development of neonatal shock include hypovolemia, myocardial dysfunction, abnormal peripheral vasoregulation, or a combination of two or all three of these factors.

Hypovolemia

Hypovolemia may be absolute (loss of intravascular volume), relative (increased venous capacitance), or combined, such as is often seen in septic shock (Fig. 51.7). Hypovolemia results in cardiovascular compromise primarily by the decrease in cardiac output (systemic blood flow) caused by the decrease in preload. In addition, if blood loss is the primary cause of hypovolemia, the associated decrease in oxygen-carrying capacity contributes to the development of the circulatory compromise. Because of the weak relationship between blood pressure and blood volume in hypotensive preterm neonates, hypovolemia was traditionally thought to be a relatively uncommon primary cause of circulatory compromise, especially during the first postnatal day (Barr et al., 1977; Wright and Goodhall, 1994). However, given the difficulty in assessing intravascular volume especially during the transition, hypovolemia can be difficult to detect clinically. Therefore the true contribution of hypovolemia to circulatory failure is uncertain. Recent studies comparing the effects of delayed umbilical cord clamping or cord milking with immediate cord clamping found increased blood pressure and decreased use of vasopressors/inotropes, suggestive of improved hemodynamic status in the delayed cord clamping and cord milking groups (Rabe et al., 2012; Hooper et al., 2015; Katheria et al., 2015). In addition, patients with delayed cord clamping have higher blood volume, and fewer of them receive transfusions (Farrar et al., 2011; Rabe et al., 2012; Backes et al., 2014). These findings imply that hypovolemia might be a more common presentation in preterm neonates who receive standard care with immediate cord clamping than previously thought.

Absolute hypovolemia in the newborn can be due to several conditions. Intrapartum fetal blood loss is usually caused by open bleeding from the fetal side of the placenta, and therefore it is likely to be detected. More difficult to diagnose is the closed bleeding of an acute fetomaternal hemorrhage or an acute fetoplacental hemorrhage. The latter can occur during delivery where the umbilical cord comes under some pressure (breech presentation or nuchal cord). Because the umbilical vein is more compressible, it is occluded before the artery, and blood continues to be pumped into the placenta. If the cord is clamped early, the excess blood remains trapped in the placenta. This probably happens to some degree in all babies with tight nuchal cords, who, as a group, have lower hemoglobin levels (Shepherd et al., 1985). However, in some

neonates a tight nuchal cord may also cause severe circulatory compromise (Vanhaesebrouck et al., 1987). Postnatally, acute blood loss may occur from any site and is frequently associated with perinatal infections or severe asphyxia-induced endothelial damage and the ensuing disseminated intravascular coagulation. Finally, acute abdominal surgical problems and conditions associated with the nonspecific inflammatory response syndrome and subsequent increased capillary leak with loss of fluid into the interstitium can lead to significant decreases in the circulating blood volume. Iatrogenic causes of absolute hypovolemia include inadequate fluid replacement in conditions of increased insensible losses in the very preterm neonate and gastroschisis before closure of the defect and the inappropriate use of diuretics.

Relative hypovolemia (i.e., a decrease in the effective circulating blood volume) may occur in pathologic conditions leading to vasodilation such as those associated with the nonspecific inflammatory response syndrome (sepsis, necrotizing enterocolitis, asphyxia, major surgical procedures, use of extracorporeal membrane oxygenation). In addition, the use of afterload-reducing agents (e.g., milrinone, prostaglandin E2) may cause significant vasodilation (especially venodilation), thereby decreasing the effective circulating blood volume.

Finally, absolute and relative hypovolemia most frequently occur in conditions associated with nonspecific inflammatory response syndrome, such as sepsis, asphyxia, and major surgical procedures.

Myocardial Dysfunction

Both systolic and diastolic cardiac dysfunction can cause circulatory failure. As echocardiographic assessment of diastolic function is complex and not well established, except in extreme cases, diastolic dysfunction often goes undetected. Nevertheless, diastolic dysfunction is recognized to be the primary cause of circulatory failure associated with hypertrophic cardiomyopathy in infants of diabetic mothers. In addition, extrinsic factors such as pericardial effusion evolving to tamponade and tension pneumothorax can lead to diastolic dysfunction. Systolic dysfunction, on the other hand, is easier to diagnose by echocardiography.

Acquired heart disease presenting as circulatory compromise includes cardiomyopathies, postasphyxial myocardial dysfunction due to hypoxic–ischemic injury, viral myocarditis, and myocardial dysfunction in the late stages of septic shock. For more details on structural heart disease and cardiomyopathies, see Chapter 55.

Among the different types of congenital heart disease, structural heart defects that produce a ductus arteriosus–dependent systemic circulation, such as hypoplastic left-sided heart syndrome, critical coarctation, and critical aortic stenosis, if not diagnosed prenatally or immediately after delivery, classically present as acute circulatory compromise with pallor, tachypnea, impalpable pulses, and hepatomegaly as the ductus starts closing. The presentation may be initially misdiagnosed as sepsis.

Abnormal Peripheral Vasoregulation

Peripheral vasodilation causes circulatory compromise by resultant decreases in perfusion pressure. However, patients with intact myocardial function usually have normal or high cardiac output as they attempt to compensate for the decrease in organ blood flow. Pathologic peripheral vasodilation in neonates occurs primarily in conditions associated with nonspecific inflammatory response syndrome, such as sepsis, necrotizing enterocolitis, severe asphyxia, major surgical procedures, use of extracorporeal membrane oxygenation, or respiratory distress syndrome of prematurity. It is of clinical importance that preterm neonates born to mothers with

chorioamnionitis, especially if they have evidence of funisitis (fetal vessel inflammation), frequently have hypotension and hyperdynamic, vasodilatory cardiovascular compromise at birth or shortly afterward (Yanowitz et al., 2002, 2004, 2006).

Clinical Presentations of Shock in Neonates Associated With Multiple Etiologic Factors

Transitional Circulatory Compromise of the Very Preterm Neonate

The transitional circulatory changes at birth and in the first 12 to 24 hours after birth denote a period of unique circulatory vulnerability especially for the extremely preterm infant. As mentioned earlier, the timing of umbilical cord clamping has a significant effect on volume status and systemic hemodynamics. During normal postnatal adaptation, pulmonary vascular resistance falls, systemic vascular resistance rises with removal of the placenta from the circulation, the ductus arteriosus closes, and the foramen ovale is closed by the reversal of the atrial pressure gradient. During this time frame, the left ventricle must double its output. Given that the very preterm infant's cardiovascular system is adapted to the low-resistance intrauterine environment and its myocardium is immature, it is not surprising that it has difficulties during this critical period. In addition, as discussed earlier, developmentally regulated factors such as the state of vital organ assignment of the forebrain and cerebral oxygen demand–flow coupling make cardiovascular adaptation of the very preterm neonate an even more complex process. It is important to note that there is much more to understand about the complex interactions between immediate postnatal cardiovascular adaptation and immaturity, organ development, myocardial and vasoregulatory function, and vital organ assignment.

Low Preload and Immediate Umbilical Cord Clamping

Following delivery of a preterm infant, immediate clamping of the umbilical cord has been the standard of clinical care since the 1960s. However, as this practice is associated, among other factors, with inadequate transfer of blood from the placenta to the newborn, the approach to the timing of cord clamping has started to change. Recent findings have demonstrated that delayed umbilical cord clamping increases blood volume (preload), confers a more gradual rise in left ventricular afterload, and allows a smoother cardiorespiratory transition in the first few minutes after birth. These beneficial effects are likely responsible for the observation that preterm infants delivered with delayed cord clamping have higher brain tissue oxygen saturation and indices of CBF compared with those delivered with immediate cord clamping (Baenziger et al., 2007; Sommers et al., 2012). Initiation of breathing seems to be a key factor in aiding effective placental transfer of blood to the infant (Bhatt et al., 2013; Boere et al., 2015). However, as cord milking also improves hemodynamics and indices of CBF (SVC flow) (Hosono et al., 2009; Katheria et al., 2015), it appears that the most important factor in enhancing smoother hemodynamic transition and reducing the incidence of circulatory compromise during the transitional period is placental transfusion itself rather than the process of maintaining placental connection to preterm infants for a period immediately after birth.

The improvement in systemic hemodynamics with placental transfusion, including CBF, explains, at least in part, the finding of lower incidence of overall periventricular/intraventricular

hemorrhage (P/IVH) in preterm infants who undergo delayed cord clamping or cord milking compared with those who undergo immediate cord clamping (Mercer et al., 2006; Rabe et al., 2012; Backes et al., 2014). This finding along with a host of other benefits has initiated support for the use of delayed cord clamping by the American College of Obstetricians and Gynecologists (Committee on Obstetric Practice, American College of Obstetricians and Gynecologists, 2012) as well as by the Neonatal Resuscitation Program (Perlman et al., 2015). However, little is known about the optimal timing of cord clamping after delivery, the populations who benefit most from it, the position of the baby relative to the placenta, and the preferred mode of respiratory support before the cord is clamped. Furthermore, as a recent study showed some evidence of better response to milking compared with delayed cord clamping in preterm infants born by cesarean delivery (Katheria et al., 2015), more needs to be understood about the most appropriate way or ways to promote placental transfusion.

Myocardial Dysfunction and High Afterload

As mentioned earlier, the abrupt increase in left ventricular afterload following the sudden removal of the low-resistance placenta can be detrimental to the immature myocardium. There is a normal inverse linear relationship between the heart rate–corrected velocity of circumferential shortening (an index of contractility) and wall stress (an index of afterload). Even in term infants the myocardium is particularly sensitive to a rise in afterload, as demonstrated by a steeper inverse relationship between the heart rate–corrected velocity of circumferential shortening and wall stress compared with that in mature heart of older children (Rowland and Gutgesell, 1995). As preterm infants have anatomically and functionally immature myocardium, they are especially prone to systolic dysfunction. Indeed, the ensuing systolic dysfunction is thought to be one of the key factors in the development of low cardiac output in a subset of high-risk preterm infants during the transitional period (Osborn et al., 2007; Noori and Seri, 2015b).

Patent Ductus Arteriosus

As mentioned earlier, a significant proportion of preterm infants fail to constrict and close their ductus arteriosus. The impact of prolonged left-to-right shunting on the pulmonary circulation and the resultant systemic hypoperfusion are discussed in Chapter 54. However, even a short exposure to significant left-to-right PDA shunting in susceptible preterm infants can result in pulmonary hemorrhage and systemic hypoperfusion and hypotension during the transitional period. Furthermore, it is important to recognize that ductal shunting can have significant hemodynamic effects before it can be clinically detected. In healthy term neonates, PDA shunting changes to predominantly left to right within the first few minutes after birth (Noori et al., 2012). Although no data are available on PDA shunting at the time of delivery in preterm infants, by 5 hours after birth the vast majority of these patients have a completely or predominantly left-to-right shunt across the ductus arteriosus (Kluckow and Evans, 1995). The heart significantly increases its output in an attempt to compensate for the left-to-right ductal shunt. There is some evidence that, at least in a subset of preterm neonates, this compensation may be inadequate in the early postnatal period (Kluckow and Evans, 2000c; Noori et al., 2012). Indeed, preterm infants with low SVC flow have a larger PDA compared with those with normal SVC flow but only during the first 6 to 12 hours postnatally (Kluckow and Evans, 2000c). This suggests that inadequate adaptation to ductal shunting early after birth may contribute to cerebral hypoperfusion immediately

after delivery. Therefore with regard to the negative effect of PDA shunting on CBF, the most vulnerable period might be the first 6 to 12 hours of postnatal life (Noori and Seri, 2015b).

Respiratory Support and Hemodynamics

Extremely preterm infants commonly require respiratory support during the transitional period. However, positive intrathoracic pressure associated with the provision of respiratory support could potentially adversely affect venous return and result in decreased preload and cardiac output. In poorly compliant lungs (e.g., in patients with respiratory distress syndrome before administration of surfactant) the effect on venous return is minimal (de Waal et al., 2009). However, in compliant lungs, venous return can be severely impaired (Hausdorf and Hellwege, 1987). These findings highlight the importance of understanding the possible adverse effects of provision of respiratory support on pulmonary and systemic hemodynamics so that the most appropriate settings and weaning strategies can be used.

Permissive hypercapnia is a lung-protective strategy commonly used in an attempt to reduce the need for ventilator support in preterm infants (Miller and Carlo, 2007; van Kaam et al., 2013). However, little is known about the safety and the optimal carbon dioxide (CO₂) range of permissive hypercapnia (Thome et al., 2006; Noori et al., 2014b). In addition to its direct effects on cerebral hemodynamics (see later) and because of the immature renal compensatory mechanisms of the preterm neonate, permissive hypercapnia invariably leads to severer respiratory acidosis during the transitional period. The effects of acidosis on the cardiovascular system in the neonate in general and the preterm infant in particular are largely unknown (Noori et al., 2013). In adults, respiratory acidosis decreases myocardial contractility and systemic vascular resistance but, presumably because of the resultant lower afterload, also increases cardiac output (Weber et al., 2000). In hemodynamically stable preterm infants, a recent study showed no association between acidic pH and indices of myocardial function and contractility and systemic vascular resistance during the first 3 days postnatally (Noori et al., 2013). While this finding might be considered reassuring, it is important to note that the cardiovascular effects of an acidic pH in hemodynamically unstable neonates are not known.

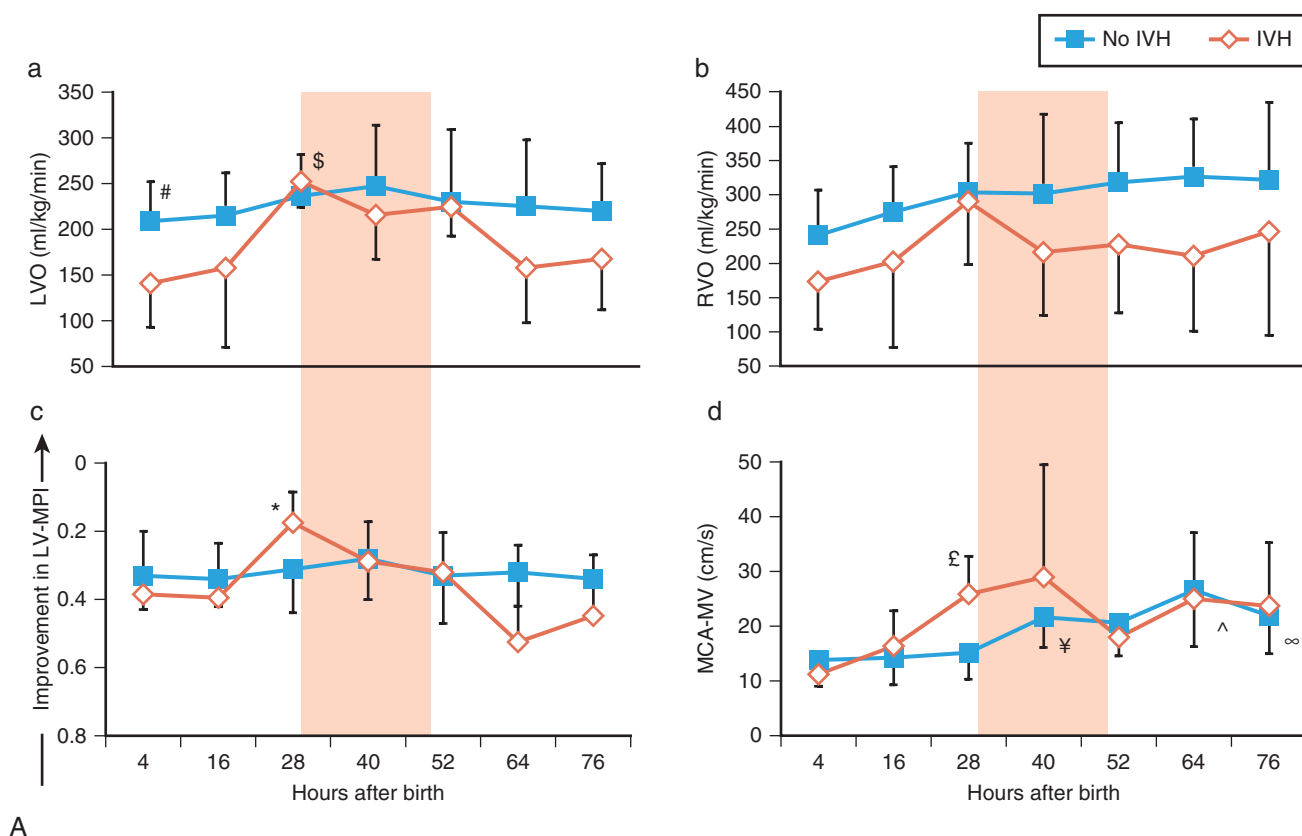

Ischemia–Reperfusion

It has long been recognized that preterm infants with low CBF during the immediate postnatal period are at greater risk of developing P/IVH (Meek et al., 1999b). The decrease in CBF in these patients has been documented with use of different techniques (Kluckow and Evans, 2000c; Kissack et al., 2004). In addition, in some patients with low SVC flow, it was observed that P/IVH occurred after increases in SVC flow (Kluckow and Evans, 2000c). Similarly, higher cerebral regional oxygen saturation (CrSO₂) and lower oxygen extraction were recently reported in preterm infants during 24 hours before detection of P/IVH (Alderliesten et al., 2013). These findings might suggest that cerebral reperfusion leads to development of P/IVH. However, these observations are not universal as others have documented only persistently low CBF for more than week after birth (Verhagen et al., 2010). Recent advancement in NIRS technology has made continuous monitoring of indices of CBF feasible (see section on *diagnosis*). When, during the first 3 days postnatally, extremely preterm infants were comprehensively evaluated by, among other methods, continuous monitoring of CrSO₂ by NIRS and periodic cardiac function, systemic perfusion, and cerebral perfusion assessments by

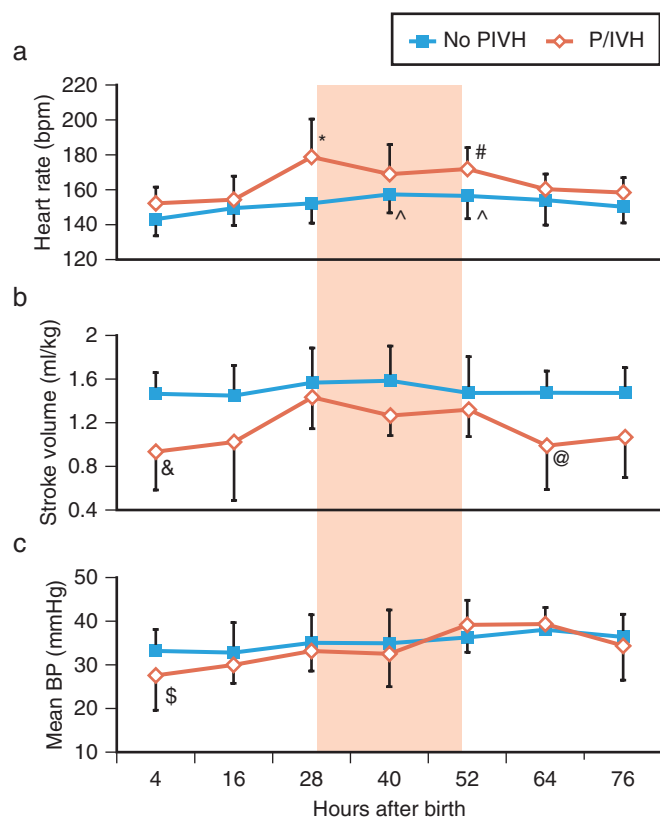

ultrasonography, a phase of initial cerebral ischemia and lower systemic perfusion (Fig. 51.8) followed by a reperfusion phase preceding the detection of P/IVH was documented (Fig. 51.9; Noori et al., 2014a). The cerebral hypoperfusion and reperfusion coincided with low cardiac output and improvement in cardiac output, respectively.

Although, as mentioned earlier, myocardial dysfunction may contribute to the occurrence of low cardiac output, this finding has not been consistently documented (Osborn et al., 2007; Noori et al., 2014a). The initial low cardiac output is likely multifactorial, and decreased preload, especially with immediate cord clamping and/or with the use of inappropriately high mean airway pressure, poor myocardial contractility in the setting of myocardial immaturity and high afterload, and uncompensated ductal shunting are among the suggested pathogenic factors (Noori and Seri, 2015a). On the other hand, the reperfusion phase could also be a consequence of

the recovery of cardiac function potentiated by hypercapnia and/or the inappropriate titration of medications used in the management of neonatal shock. As increases in CO_2 result in increases in CBF, permissive hypercapnia may exaggerate the reperfusion phase. Epidemiologic data reveal an association between hypercapnia and P/IVH (Kaiser et al., 2006; Fabres et al., 2007; Ambalavanan et al., 2015). Furthermore, PaCO_2 values above the low-to-mid 50 mmHg strongly correlate with indices of increased CBF suggesting a significant rise in CBF with the use of more extreme levels of permissive hypercapnia (Noori et al., 2014b). Hypercapnia also attenuates CBF autoregulation, likely putting preterm infants at higher risk of uncontrolled increases in CBF (Kaiser et al., 2005; Noori et al., 2014a). As hypotensive preterm infants also have impaired CBF autoregulation (Munro et al., 2004), excessive and abrupt increases in blood pressure with the inappropriate use of vasopressors/inotropes can result in sudden, excessive increases in

• **Fig. 51.8** Changes in Selected Hemodynamic Parameters (Left and Right Ventricular Output, Left Ventricular Myocardial Performance Index, Middle Cerebral Artery Mean Velocity, Heart Rate, Left Ventricular Stroke Volume, and Mean Blood Pressure) During the First 76 Hours in Very Preterm Neonates With and Without Periventricular/Intraventricular Hemorrhage. (A) Changes in left ventricular output (LVO; a), right ventricular output (RVO; b), left ventricular myocardial performance index (LV-MPI; c), and middle cerebral artery mean velocity (MCA-MV; d) in the two groups during the study. There was a trend for a lower LVO in the periventricular/intraventricular hemorrhage (P/IVH) group at the baseline with a trend for an increase before the occurrence of P/IVH (highlighted in pink). Lower LV-MPI (i.e., better function) and higher MCA-MV in the P/IVH group preceded the occurrence of P/IVH. The pattern of changes in LVO between the two groups tended to be statistically significant ($P = .068$), whereas that in RVO, LV-MPI, and MCA-MV did not reach statistical significance between the two groups. Statistically significant differences between groups, $P = .04$ (asterisk) and $P = 0.016$ (pound sign); no-P/IVH group compared with the baseline, $P = .02$ (yen sign), $P < .0001$ (caret), and $\infty P = .044$ (infinity sign). Differences approaching statistical significance and suggesting a difference between the groups, $P < .055$ (number sign), and within the P/IVH group compared with the baseline, $P = .07$ (dollar sign). The values represent the mean \pm standard deviation of the data obtained on entry into the study and every 12 hours thereafter.

B

• **Fig. 51.8, cont'd** (B) Changes in heart rate (a), left ventricular stroke volume (b), and mean blood pressure (BP; c) in the two groups during the study. Heart rate significantly increased in the no-P/IVH group (ANOVA $P = .004$), while there was only a trend for an increase in the P/IVH group (ANOVA $P = 0.051$) during the study. Compared with the no-P/IVH group, left ventricular stroke volume in patients in the P/IVH group was lower at the baseline but similar before the occurrence of P/IVH. Mean blood pressure (c) tended to increase in the P/IVH group (ANOVA $P = 0.052$), while it remained unchanged and relatively stable in the no-P/IVH group (ANOVA $P = 0.2$). In addition, mean blood pressure at baseline also tended to be lower in patients in the P/IVH group. The pattern of changes in heart rate and stroke volume, but not in mean blood pressure, was different between the two groups. See the text for details. No-P/IVH group compared with the baseline, $P = .007$ (caret); Between groups, $P = .004$ (asterisk), $P = 0.03$ (number sign), $P = .007$ (ampersand), $P = .048$ (at symbol), and $P = 0.085$ (dollar sign). The values represent the mean \pm standard deviation of the data obtained on entry into the study and every 12 hours thereafter. The area highlighted in pink represents the period when P/IVH occurred. bpm, Beats per minute; IVH, intraventricular hemorrhage. (Courtesy Noori S, McCoy M, Anderson MP, et al. Changes in cardiac function and cerebral blood flow in relation to peri/intraventricular hemorrhage in extremely preterm infants. *J Pediatr.* 2014;164:264–270.)

CBF, which in turn might potentiate the reperfusion injury (Noori and Seri, 2015b).

Vital Organ Assignment

As discussed earlier, compared with blood supply to most other organs, blood supply to the brain is relatively protected during hypoxia by its vascular property; hence the brain is considered a vital organ. However, this vascular capacity undergoes a maturation process, with the vessels of the forebrain (including cerebral cortex and basal ganglia) reacting like those of a nonvital organ in very preterm infants during the early postnatal period (Hernandez

B

• **Fig. 51.9** Changes in cerebral regional oxygen saturation (rSO₂) and cerebral fractional oxygen extraction (CFOE) in two groups with (red) and without (blue) periventricular/intraventricular hemorrhage (P/IVH) during first 3 days postnatally. The no-P/IVH group exhibited stable cerebral rSO₂ (A) and CFOE (B) values, while the P/IVH group exhibited a characteristic pattern of changes. The P/IVH group had lower cerebral rSO₂ and higher CFOE during the first 12 hours of the study, followed by normalization of these parameters (highlighted in green) just before the two study periods when P/IVH was detected (highlighted in pink). These findings suggest initial cerebral hypoperfusion followed by a period of reperfusion before the occurrence of the bleeding. After the second study period, cerebral rSO₂ decreased and CFOE increased, suggesting a decrease in cerebral blood flow during and after the development of P/IVH. Statistically significant differences between the two groups, $P < .005$ (asterisk), $P < .04$ (number sign), and $P < .05$ (dollar sign). The values represent the mean \pm standard deviation of the data obtained in each 12-hour data collection period. (Courtesy Noori S, McCoy M, Anderson MP, et al. Changes in cardiac function and cerebral blood flow in relation to peri/intraventricular hemorrhage in extremely preterm infants. *J Pediatr.* 2014;164:264–270.)

et al., 1982; Ashwal et al., 1984; Victor et al., 2006a; Noori et al., 2009). This developmentally regulated phenomenon has significant implications as most extremely preterm infants are in compensated or uncompensated shock, with lower systemic flow, immediately following delivery. In these infants, instead of vasodilating, the vessels of the forebrain vasoconstrict just like those of the nonvital organs (e.g., kidneys or intestine). Accordingly, immaturity of vital organ assignment in the forebrain likely contributes to the observed cerebral ischemia even in nonhypotensive extremely preterm neonates during the immediate postnatal period (see earlier).

Vasopressor-Resistant Hypotension

Although the pathologies of transitional hemodynamics described earlier may or may not present with low blood pressure (compensated versus uncompensated phase of shock), there is a group of preterm neonates in whom persistent hypotension that is resistant to conventional vasopressor/inotropic support develops (Ng et al., 2001; Seri et al., 2001; Watterberg, 2002; Ng et al., 2006; Noori et al., 2006b). The underlying systemic hemodynamic changes in this condition have also been characterized (Noori et al., 2006a). These babies are more likely to be extremely preterm babies (≤ 27 weeks) and/or have been critically ill or had a degree of perinatal asphyxia. The problem may be apparent on the first postnatal day (Ng et al., 2006) but may persist beyond that and represent a state of vasodilatory shock with normal to high systemic blood flow and possibly supranormal cardiac output (Lopez et al., 1997). There are striking analogous features of this presentation in preterm neonates to those of vasodilatory shock described in adults, particularly the lack of responsiveness to vasopressors/inotropes (Landry and Oliver, 2001). Potential mechanisms for the uncontrolled vasodilation include dysregulated cytokine release, excess nitric oxide synthesis, overactivation of the ATP-sensitive potassium channels in the vascular smooth muscle cell membrane in response to tissue hypoxia, and downregulation of the cardiovascular adrenergic receptors (Hausdorff et al., 1990; Seri et al., 2001). In the preterm infant, the foregoing mechanisms are exacerbated by the immaturity-associated relative adrenal insufficiency (Watterberg et al., 1999; Watterberg, 2002; Cole, 2008), are exacerbated by preceding asphyxia, or may be secondary to the transitional circulatory failure as described earlier. In the term neonate an association between congenital diaphragmatic hernia and relative adrenal insufficiency has also been reported (Pittinger and Sawin, 2000).

Sepsis

Although clinical evidence of circulatory compromise is a leading feature of many infectious processes in the newborn, only limited data are available on the hemodynamics in neonatal septic shock (de Waal and Evans, 2010; Saini et al., 2014). In older individuals, two distinct hemodynamic patterns occur: warm shock, characterized by loss of vascular tone, increased systemic blood flow, and low blood pressure, and cold shock, characterized by increased vascular tone, low systemic blood flow, and eventually falling blood pressure. Cold shock has been well described in the newborn (Meadow and Rudinsky, 1995), whereas the warm shock pattern is more difficult to recognize clinically unless the blood pressure and the cardiovascular status in general are being closely monitored. A recent study in preterm infants demonstrated high cardiac output and low systemic vascular resistance consistent with the presence of warm shock (de Waal and Evans, 2010). Another study also found higher left ventricular output in preterm infants with septic shock compared with a control group, suggestive of vasodilation as the dominant pathophysiologic factor (Saini et al., 2014). However, because a significantly higher proportion of neonates in the septic group had a PDA, the increase in left ventricular output in that study could have been due, at least in part, to the presence of the left-to-right shunt rather than high systemic flow *per se*. The mediators of neonatal warm septic shock remain unclear, but in adult sepsis, dysregulated cytokine release and upregulated nitric oxide production as well as deficiency of vasopressin production play an important role (Landry and Oliver, 2001). The significance of this to newborn sepsis remains unclear, but it may have relevance

to the vasopressor-resistant hypotension seen in preterm babies (Ng et al., 2001; Seri et al., 2001; Ng et al., 2006; Noori et al., 2006a, 2012).

Pulmonary Hypertension With or Without Meconium Aspiration Syndrome

Term neonates with severe respiratory failure and pulmonary hypertension have a high incidence of low ventricular outputs (Evans et al., 1998). The low-output state is commonest in the early course of the disease, resolving spontaneously with time and/or clinical improvement. The causes of such circulatory compromise are probably multifactorial (Jain and McNamara, 2015) but include abnormal postnatal cardiovascular adaptation secondary to perinatal hypoxic-ischemic insult, the negative effects of positive pressure ventilation, and the systemic effect of raised pulmonary vascular resistance. In one study, low left ventricular output was a significant predictor of the need for extracorporeal membrane oxygenation in this patient population (Kinsella et al., 1992).

Diagnosis of Circulatory Compromise

There is no agreement regarding what constitutes the gold standard in diagnosing circulatory compromise in the neonate. However, blood pressure remains the most commonly used criterion for diagnosis and initiation of treatment in this patient population (Batton et al., 2013; Stranak et al., 2014). As mentioned earlier, available data suggest that sole reliance on blood pressure can lead to inaccurate or, in other cases, significantly delayed diagnosis of circulatory compromise, especially in the very preterm infant during the immediate postnatal period. On the other hand, it is clear from the observations regarding vasodilatory shock that continuous blood pressure monitoring is imperative. The other commonly used clinical signs of circulatory compromise, such as increased heart rate, slow skin CRT, increased core-peripheral temperature difference, low urine output, and acidosis due to increased lactate production, aid in establishing the diagnosis of circulatory compromise in the preterm or term infant but also have significant limitations.

With recent advancements in biomedical technology, the armamentarium of devices for bedside cardiorespiratory monitoring has broadened, enabling the clinician to perform intermittent and/or continuous assessment of systemic and regional perfusion in neonates (Table 51.1). Although they are used mostly for research applications, these devices have also started to be increasingly used for routine clinical care (Azhibekov et al., 2015).

Heart Rate and Blood Pressure

Heart rate is continuously, accurately, and routinely monitored in neonates requiring admission to neonatal intensive care units. Because many factors other than those regulating the cardiovascular system affect heart rate, it has a limited yet widely used role in the diagnosis of circulatory compromise. In babies with invasive arterial access, continuous and accurate measurement of blood pressure is routinely done. The accuracy of the noninvasive oscillometric method is less certain, especially when severe hypotension develops. Normal ranges for blood pressure in babies of different gestations have been defined in the literature (epidemiologic definition of hypotension), and it is clear that gestation and postnatal age are the dominant influences on blood pressure (Lee et al., 1999; Nuntnarumit et al., 1999; for a comprehensive review, see

TABLE 51.1**Systemic and Regional Hemodynamic Parameters Most Commonly Monitored in Neonates**

| | Parameter | Technology/Method | Purpose and Acquisition (C, I, or C/I) |
|----------------------------------|--|--|--|
| Systemic perfusion (BP and CO) | Heart rate | ECG (electrodes) | In conjunction with stroke volume gives flow status (C) |
| | BP | Arterial line/cuff (oscillometry; Doppler ultrasonography) | Perfusion pressure (C/I) |
| | Stroke volume/CO | Echocardiography IEC | Systemic, pulmonary (CO), and organ blood flow, cardiac function (I) Systemic blood flow (CO) (C) |
| Systemic oxygenation | SPo ₂ | Pulse oximetry | Oxygenation on the arterial side (C) |
| CO ₂ status | TCOM | CO ₂ diffusion through skin | Effect on cerebral vasculature (changes in CBF) (C) |
| Regional perfusion | Regional O ₂ saturation | NIRS | Tissue oxygenation and (indirectly) organ perfusion (C) |
| Peripheral perfusion | Microcirculation (oxygenation; blood flow velocity; capillary recruitment) | Visible light technology | Peripheral perfusion (C) |
| | | Laser Doppler flowmetry | Peripheral perfusion (C) |
| | | OPS imaging and SDF imaging | Peripheral perfusion (C) |
| Indirect assessment of perfusion | Capillary refill time | Visual | Systemic perfusion (indirectly) (I) |
| | ΔT (C–P) | Temperature | Systemic perfusion (indirectly) (I) |
| | Color | Visual | Peripheral perfusion (I) |
| Organ function | Brain electrical activity | aEEG | Assessment of brain activity (C) |
| | Urine output | Urinary catheter | Assessment of renal function (I) |

Various components of systemic perfusion (blood pressure [BP] and cardiac output [CO]) and oxygenation, carbon dioxide production and elimination, regional (organ) and peripheral (microcirculation) perfusion, and organ function (amplitude-integrated electroencephalography [aEEG]) that can be monitored at the bedside along with the indirect methods used in clinical practice to assess perfusion and organ function. Acquisition can be continuous (C), intermittent (I), or both (C/I). CBF, Cerebral blood flow; ΔT (C–P), core and peripheral temperature difference; ECG, electrocardiogram; IEC, impedance-based electrical cardiometry; NIRS, near-infrared spectroscopy; OPS, orthogonal polarization spectral; SDF, side-stream dark field; TCOM, transcutaneous CO₂ monitoring.

• **Fig. 51.10** Gestational Age- and Postnatal Age-Dependent Nomogram for Mean Blood Pressures in Neonates During the First 3 Days of Postnatal Life. The nomogram is derived from continuous arterial blood pressure measurements obtained from 103 neonates with gestational ages between 23 and 43 weeks. Each line represents the lower limit of the 80% confidence interval of the mean blood pressure for each gestational age group. Thus 90% of infants for each gestational age group are expected to have a mean blood pressure equal to or greater than the value indicated by the corresponding line (the lower limit of the confidence interval). (Courtesy Nuntnarumit P, Yang W, Bada-Ellzey HS. Blood pressure measurements in the newborn. *Clin Perinatol.* 1999;26:981–996.)

Engle, 2012). The nomogram from the data of Nuntnarumit et al. in Fig. 51.10 shows the 10th percentile for mean blood pressure of babies from different gestations at different postnatal ages.

The normal gestational age- and postnatal age-dependent blood pressure range is not known, primarily because it is affected by

additional factors, such as disease severity, history of perinatal insult, presence of infection or ductal shunting, and interindividual variations (Engle, 2012; McLean et al., 2012). In addition to the epidemiologic definition of hypotension, increasing severity of hypotension can be defined from a pathophysiologic standpoint as the blood pressure at which CBF becomes pressure passive (autoregulatory blood pressure threshold; the definition used for the pediatric and adult patient population), brain function is affected (functional blood pressure threshold), and tissue ischemia develops (ischemic blood pressure threshold; Fig. 51.11) (McLean et al., 2012). Some data are available for the autoregulatory and functional blood pressure threshold in very preterm neonates during the first few postnatal days (Munro et al., 2004; Victor et al., 2006b). However, there is no information on the ischemic threshold in very preterm neonates, and very little is known about these pathophysiologic measures of hypotension in the term neonate or in any neonate beyond the transitional period. Perhaps the best method to define hypotension would be the demonstration of causation between gestational age- and postnatal age-dependent blood pressures and clinically relevant outcome measures such as mortality or long-term neurodevelopmental disability. However, because there are no data available on this interaction, there is uncertainty about the normative values. Besides, treatment may have its own side effects; hence there is controversy about when and how to intervene in the critically ill neonate with suspected hypotension and circulatory compromise (Barrington and Dempsey, 2006; Noori et al., 2012; Batton et al., 2016).

In clinical practice, hypotension during the first postnatal day is usually defined in one of three ways: as a mean blood pressure less than 30 mmHg, a mean blood pressure in millimeters of mercury below the patient's gestational age in weeks at the time

• **Fig. 51.11** Definition of Hypotension by Three Pathophysiologic Phenomena of Increasing Severity: Autoregulatory, Functional, and Ischemic Thresholds of Hypotension. CBF, Cerebral blood flow; MBP, mean blood pressure. (Courtesy McLean CW, Noori S, Cayabyab R, Seri I. Cerebral circulation and hypotension in the premature infant—diagnosis and treatment. In Perlman JM, ed. *Controversies in Neonatal Neurology*. Philadelphia, PA: Saunders; 2012:3–25.)

of birth (Lee et al., 1999), or, more recently, a blood pressure that is accompanied by clinically detectable evidence of circulatory compromise (decreased urine output, poor peripheral perfusion, and/or lactic acidosis) (Dempsey et al., 2009). As mentioned earlier, there is only a weak relationship between mean blood pressure and SVC flow, a surrogate measure of systemic blood flow in preterm neonates with the fetal channels open in the immediate postnatal period (Kluckow and Evans, 1996; Lopez et al., 1997; Kluckow and Evans, 2000a; Pladys et al., 1999). Thus if blood pressure alone is used to guide treatment, patients in the unrecognized compensated phase of shock may not be treated appropriately. For instance, in the extremely preterm neonate with mean blood pressure between 20 and 40 mmHg in the immediate postnatal period, the state of systemic blood flow and CBF is unclear based on the blood pressures alone. Recent advances in our ability to apply complex, continuous cardiovascular monitoring providing data in absolute numbers using impedance-based electrical cardiometry, NIRS, and amplitude-integrated EEG combined with the intermittent use of Doppler flow measures hold the promise of gaining a better understanding of the hemodynamic changes occurring during transition and beyond in the neonatal patient population (Noori et al., 2009; Soleymani et al., 2012).

Capillary Refill Time

Several studies have attempted to validate this widely used clinical tool for accuracy. However, there is no validated standard for assessing decreased peripheral perfusion and its relationship to systemic flow in the newborn. Further, in the different types of shock (warm shock vs cold shock) the state of peripheral perfusion is different (vasodilation vs vasoconstriction). Hence it is impossible to objectively assess the practical utility of this clinical tool in neonates. Accordingly, in VLBW neonates a poor correlation was found between CRT, assessed on the forehead, sternum, and toe, and mean blood pressure, urine output, and SVC flow (Miletin et al., 2009). An earlier study documented a similar lack of tight relationship in VLBW neonates; only when CRT was more than 5 seconds did it have any clinically relevant degree of specificity

(Osborn et al., 2001). Although a CRT of 3 seconds or less is traditionally accepted as normal, a CRT of 4.23 ± 1.47 seconds with a range of 1.63 to 8.78 seconds was reported in a large population of healthy newborns during the first 72 hours postnatally. CRT does not appear to change during the first 72 hours postnatally in healthy term newborns (Raju et al., 1999). Environmental, axillary, hand, and foot temperatures have been reported to indirectly relate to CRT (Raju et al., 1999). The duration of the pressure applied when CRT is being measured affects the measurement in term neonates less than 4 hours after delivery (LeFlore and Engle, 2005). That study also found an unanticipated moderate, direct correlation between blood pressure and CRT, with a prolongation of CRT at higher blood pressures in this patient population (LeFlore and Engle, 2005). In general, interobserver variability has been reported to be fair, but a variation in the measurement among the different sites (sternum, forehead, hand, and feet) may be significant, although this issue needs to be more systematically studied.

Core–Peripheral Temperature Difference

There are few data to support the accuracy of this test in older infants (Tibby et al., 1999). In preterm neonates of less than 30 weeks' gestational age, there was also no relationship between this measure and SVC flow in the immediate postnatal period (Osborn et al., 2001). However, because SVC flow measurements have their limitations, these studies need to be repeated when a more accurate and continuous measure of systemic blood flow assessment becomes available for neonates with fetal channels open.

Low Urine Output and Hyperkalemia

Urine output is a frequently used clinical measure to assess renal perfusion and function. However, because urine output is low during the first postnatal day as a result of delivery-associated increases in the levels of stress hormones (catecholamines, vasopressin, renin–angiotensin) causing renal vasoconstriction and increased tubular reabsorption of sodium and water, its value in assessing compensated shock during the transitional period is limited. After

the first 2 to 3 days, however, a decrease in urine output may be the earliest clinical sign of compensated shock in neonates of all gestational ages. In addition, in very preterm infants a strong relationship has been documented between low SVC flow and subsequent low urine output and hyperkalemia (Kluckow and Evans, 2001). However, because hyperkalemia may occur in the very preterm neonate without oliguria (i.e., nonoliguric hyperkalemia of the extremely preterm neonate) (Vemgal and Ohlsson, 2007), and because there could be other causes of hyperkalemia (acidosis), hyperkalemia alone should not be used as a measure of poor systemic perfusion.

Lactic Acid, pH, and Base Excess

In very preterm infants, the relationship between low SVC flow and pH (and/or base excess) remains unclear (Holberton et al., 2012). This is likely due to lack of a strong relationship between pH, base excess, and lactic acid levels in neonates (Deshpande and Platt, 1997). However, because serum lactate levels can be sequentially followed routinely by blood gas measurements and because changes in serum lactate levels are informative of changes in the cardiovascular status, this indirect measure of cellular oxygen delivery and consumption has been used in clinical practice. Combining a CRT of more than 4 seconds with an elevated serum lactate concentration of more than 4 mmol/L has a specificity of 97% for detecting a low SVC flow state in VLBW neonates during the first postnatal day (Miletin et al., 2009). One needs to keep in mind though that a given serum lactate level primarily represents past hemodynamic events and not necessarily the present state of cardiovascular function. Thus as with urine output, by the time lactic acidosis develops and is detected, the initiating event may or may not be present anymore. It is not a surprise therefore that rising lactate levels are more predictive of adverse outcome than a high value early on followed by a subsequent decline (Deshpande and Platt, 1997).

Organ Blood Flow

With the use of Doppler ultrasonography and more recently NIRS, blood flow to various organs can be assessed at the bedside. For CBF, several methods have been studied in both preterm and term neonates, including Doppler ultrasonography, xenon clearance, and NIRS (Greisen et al., 1984; Seri et al., 1998; Tysczuk et al., 1998; Tsuji et al., 2000; Toet et al., 2005, 2006; Lemmers et al., 2006). Because peripheral arteries tend to be too small for size measurement, Doppler studies in such vessels are limited to parameters of velocity from which it is not possible to derive blood flow. Consequently, peripheral artery Doppler ultrasonography tends to be more useful for assessing changes over a time frame in which it is unlikely that the vessel size will have changed (Seri et al., 1998). Xenon clearance is not practical outside a research setting. However, advances in NIRS technology have allowed continuous assessment of brain, renal, mesenteric, and muscle oxygenation (i.e., blood flow) at the bedside in the critically ill neonate (Fortune et al., 2001; Lemmers et al., 2008; van Bel et al., 2008) (see the next section).

Near-Infrared Spectroscopy

NIRS uses the difference in the absorption spectra of oxygenated and deoxygenated hemoglobin to indirectly assess flow. The technology has been very useful as a research tool (Tysczuk et al., 1998;

Meek et al., 1999b; Tsuji et al., 2000; Fortune et al., 2001; Lemmers et al., 2008; van Bel et al., 2008; Caicedo et al., 2011; Alderliesten et al., 2013; Noori et al., 2014a; Verhagen et al., 2010). In addition, with better understanding of biophysical principles that govern light behavior in tissues, and the associated advances in software algorithms and sophisticated NIRS probe development, continuous assessment of regional tissue oxygenation (rSO_2) has become available and gained evidence-based application in neonatal intensive care (Adcock et al., 1999; Andropoulos et al., 2004; Lemmers et al., 2008; Nagdyman et al., 2008; van Bel et al., 2008; da Costa et al., 2015).

Commercially available monitors with up to four channels can be now applied to infants, typically on the forehead to gauge cerebral rSO_2 and over the flank, felt to be measuring renal rSO_2 . Although more validation is needed with use of invasive measurements (Nagdyman et al., 2008; Rhee et al., 2012), it is evident that when cardiac output and/or mean arterial blood pressure fall, renal rSO_2 declines. First, cerebral rSO_2 may be preserved, but interference with global CBF can also be detected with this monitor, provided that certain conditions are met. These monitors are useful during cardiac surgical procedures on infants (Andropoulos et al., 2004; Azakie et al., 2005; Farouk et al., 2008), where precipitous drops in cerebral rSO_2 may be the only warning of a malpositioned venous or arterial cannula while cardiopulmonary bypass is being used. In addition, emerging findings suggest that the monitoring of rSO_2 in critically ill term and preterm neonates without congenital heart disease during transition to extrauterine life (van Bel et al., 2008) and during treatment of various conditions, such as a PDA in preterm neonates (Lemmers et al., 2008; Cayabyab et al., 2009) or asphyxia in infants with or without cooling (Meek et al., 1999a; Toet et al., 2006; Ancora et al., 2009), and in term neonates receiving extracorporeal membrane oxygenation (van Heijst et al., 2004; Fenik and Rais-Bahrami, 2009) provides clinically useful information (van Bel et al., 2008; da Costa et al., 2015). Whether titration of therapy based on rSO_2 measurements in neonates with critical conditions other than congenital heart disease requiring surgery (Andropoulos et al., 2004) improves patient outcomes remains unknown (Hyttel-Sorensen et al., 2015). In our experience, however, renal rSO_2 reliably declines well before signs of uncompensated shock, such as hypotension or acidosis, develop (see later discussion), enabling earlier intervention (Azhibekov et al., 2014).

Echocardiographic Systemic Blood Flow Measures

In the mature circulation, systemic blood flow is the cardiac output. Although the output of both ventricles will be the same, cardiac output is traditionally measured from the left ventricular output. In clinical practice, Doppler ultrasonography offers a noninvasive but noncontinuous method to measure cardiac output. Measuring blood flow directly in the pulmonary artery and ascending aorta enables us to evaluate outputs from the right ventricle and the left ventricle respectively (Alverson et al., 1982; Walther et al., 1985; Evans and Kluckow, 1996). However, as discussed earlier, in transitional circulation of the newborn, neither ventricular output will consistently reflect systemic blood flow because of the shunts across fetal channels (Evans and Iyer, 1994; Evans and Kluckow, 1996; Kluckow and Seri, 2012). Use of SVC flow as a surrogate for systemic blood flow has been a valuable research tool offering insights into hemodynamic events unfolding during the immediate postnatal period when shunting across fetal channels precludes

the use of traditional measures of systemic blood flow assessment (see earlier discussion) (Evans, 2012).

Doppler measures of left ventricular output have been validated against more invasive measures in neonates and older individuals (Mellander et al., 1987). Right ventricular output and SVC flow are less well validated but correlate well with left ventricular output in neonates with no confounding shunts (Evans and Iyer, 1994; Kluckow and Evans, 2000a; Tsai-Goodman et al., 2001). Despite this, the validity of these measures has been questioned on the basis of comparison with cardiac output thermodilution measures in critical care patients (Notterman et al., 1989). However, thermodilution itself has an intrinsic error in that the volume of the required cold saline injection influences cardiac output (Tournadre et al., 1997).

Recently, functional magnetic resonance imaging (MRI) has become the gold standard for cardiac output measurements. However, this method is used primarily for research applications, and its use for bedside assessment in neonates remains limited because of a number of technical and logistic difficulties (Groves et al., 2011). Thus finding an ideal gold standard method capable of continuous bedside cardiac output measurements in absolute numbers remains elusive.

There are significant intrinsic errors in Doppler flow measurements as well. Intraobserver variability rates of around 10% and interobserver variability rates up to 20% are common (Hudson et al., 1990; Kluckow and Evans, 2000a). Most of the error relates to the vessel size measurement that is derived from its diameter. Thus small differences are magnified in the conversion to a cross-sectional area. The other major problem of Doppler flow measurements is that there is reliance on ultrasound technology and echocardiographic skill that may not often be available 24 hours a day in many neonatal intensive care units.

In neonates, most studies quote a normal range for left and right ventricular output between 150 and 300 mL/kg per minute (Alverson et al., 1982; Walther et al., 1985; Evans and Kluckow, 1996; West et al., 2006). It is important to note that in the transitional neonatal circulation, left ventricular output can be affected by ductal shunting to a greater extent than the right ventricular output is affected by atrial shunting. Therefore right ventricular output is a better measure of low flow than left ventricular output during the first 1 to 2 days postnatally. Accordingly, a relationship has been documented between indirect measurements of systemic (and thus cerebral) perfusion such as right ventricular output and blood pressure (and cerebral function) in preterm infants during the first 2 days postnatally. This is a period when ductal shunting significantly decreases the accuracy of left ventricular output measurements reflecting systemic blood flow (West et al., 2006). SVC flow may also be used to estimate systemic flow in the early postnatal period. The normal range in well preterm babies is between 40 and 120 mL/kg per minute, with the median rising from 70 mL/kg per minute at 5 hours of age to 90 mL/kg per minute at 48 hours (Kluckow and Evans, 2000a).

In summary, the mainstay of diagnosing neonatal circulatory compromise has been a combination of blood pressure measurement and evaluation of the previously described clinical parameters. However, none of these parameters have a sufficient degree of accuracy to allow them to be relied on as the sole evaluator of systemic blood flow and tissue perfusion. Therefore the addition of echocardiographic and NIRS hemodynamic assessment to blood pressure monitoring and thorough continuous clinical evaluation of the patient are necessary to better understand changes in organ blood flow and tissue perfusion, especially in preterm neonates during the vulnerable period of immediate transition to extrauterine

life. The goal should be to maintain normal systemic blood flow and thus oxygen delivery in the presence of an acceptable blood pressure with use of the normal range for blood pressure that controls for gestational age and postnatal age and following the indirect clinical and laboratory signs of tissue perfusion (urine output, serum lactate levels, CRT). If there is no immediate access to echocardiography or NIRS technology, the clinician will have to rely on blood pressure monitoring, while recognizing the limitations of this approach. In the past few years, training in functional echocardiography for neonatologists has become available in a structured format in several programs in the United States and other countries (Kluckow et al., 2008; Mertens et al., 2011), although the medicolegal implications of such training remain largely unknown (Nguyen et al., 2016).

Measurement of Systemic Blood Flow by Electrical Impedance Velocimetry

Electrical velocimetry measures left cardiac output by continuous, noninvasive measurement of thoracic electrical bioimpedance (Osypka and Bernstein, 1999). It has also been validated against invasive methods of cardiac output measurements, with very good correlations in animals (Osthaus et al., 2007) and children (Norozi et al., 2008) and against echocardiography in healthy term neonates during the first 2 days postnatally (Noori et al., 2012c). However, its evidence-based value in pediatric clinical practice in general (Coté et al., 2015) and neonatology in particular remains to be established (Azhibekov et al., 2015).

In summary, advances in biomedical technology and development of newer sophisticated methods for comprehensive hemodynamic monitoring may provide additional insights into the pathophysiology of the cardiovascular instability and, potentially, early diagnosis of circulatory compromise; however, their use remains limited mostly to research applications, and they have yet to be validated for routine clinical use (Azhibekov et al., 2015).

Treatment of Neonatal Shock

Selection of the most appropriate treatment strategy for neonatal shock requires identification of its pathogenesis (Seri, 2001; Kluckow, 2005; Seri and Noori, 2005; Kluckow and Seri, 2012; Noori and Seri, 2012). As described earlier, the most frequent etiologic factors responsible for neonatal cardiovascular compromise are inappropriate peripheral vasoregulation, resulting in vasodilation or vasoconstriction, and dysfunction of the immature myocardium (Gill and Weindling, 1993; Seri, 1995; Osborn et al., 2002; Noori and Seri, 2005; Kluckow and Seri, 2012; Noori and Seri, 2012). Although absolute hypovolemia was thought to be a less frequent primary cause of neonatal hypotension, especially in preterm infants in the immediate postnatal period (Barr et al., 1977; Wright and Goodhall, 1994), recent findings suggest that this assumption is incorrect (Baenziger et al., 2007; Hosono et al., 2009; Sommers et al., 2012; Katheria et al., 2015).

Association Between Systemic Hypotension, Hypoperfusion, and Their Treatment and Mortality or Neurodevelopmental Impairment

The impact of hypotension and/or its treatment on mortality, brain injury, or neurodevelopmental impairment is unclear, primarily

because it is assumed that treatment will improve outcomes, and therefore the common practice has been to treat hypotension (Noori et al., 2009). Therefore there are no prospective studies evaluating the impact of untreated hypotension on clinically relevant short-term and long-term outcomes. The only presently available prospective randomized controlled trial (RCT) with a no-treatment arm found that such a trial is not feasible, at least in the United States, primarily due to difficulty in obtaining consents but also because of the clinicians' bias favoring treatment (Batton et al., 2012). To address the consent issue, some have suggested alternative approaches to traditional prerandomization consent procedures, such as waiver of informed consent with an opt-out option after randomization and inclusion (Vain and Barrington, 2012). In addition to the paucity of data from RCTs on the effect of treatment on outcome, a gestational age- and postnatal age-dependent definition of hypotension based on physiology, pathophysiology, and clinically relevant outcome measures is lacking (Engle, 2012).

One prospective RCT found that hypotensive VLBW neonates overall had a higher rate of severe P/IVH than their nonhypotensive counterparts (Pellicer et al., 2009). Hypotensive infants responding with an increase in blood pressure to targeted titration of vasopressors/inotropes had similar rates of P/IVH when compared with nonhypotensive controls. The study authors also did not find an association between abnormal ultrasound findings and the use of dopamine or epinephrine. At long-term follow-up at 2 to 3 years of age, no difference was found in the rate of abnormal neurologic status and/or developmental delay between the formerly hypotensive but successfully treated patients and the control patients. Although the results suggest that carefully titrated use of dopamine or epinephrine in hypotensive preterm infants might be safe and even have potential benefits, the small sample size and the lack of untreated hypotensive controls do not allow generalization of the findings. Of note is that although dopamine was found to be neuroprotective in the asphyxiated lamb model in a recent study (Brew et al., 2016), evidence in the human neonate is needed to establish clinical relevance of this finding.

Finally, the observation that hypotension as currently defined is unlikely to be predictive of brain injury (Limperopoulos et al., 2007; McLean et al., 2012) is important in examining the association between hypotension and its treatment and neurodevelopmental impairment.

Volume Administration

Volume administration is the most commonly used intervention for treatment of hypotension in neonates (Stranak et al., 2014). However, observations that low blood pressure is frequently associated with normal or even high ventricular output and low index of resistance (Pladys et al., 1999) and that dopamine is more effective in increasing blood pressure than volume administration (Lundstrom et al., 2000) question the effectiveness of volume administration primarily when isotonic saline is being used. Therefore particularly in the preterm infant during the immediate postnatal period, only cautious, limited fluid resuscitation has been recommended (Noori and Seri, 2015a). In addition, and as discussed earlier, expansion of blood volume by delayed umbilical cord clamping or cord milking has been shown to improve systemic hemodynamics in preterm infants (Baenziger et al., 2007; Hosono et al., 2009; Sommers et al., 2012; Katheria et al., 2015).

There are no studies yet on the safety and efficacy of the use of whole blood transfusion for treatment of hypotension and shock in neonates in the transitional period or beyond. Furthermore,

because myocardial dysfunction frequently contributes to the development of neonatal hypotension (Gill and Weindling, 1993) and aggressive volume administration in this patient population increases pulmonary, cardiovascular, gastrointestinal, and central nervous system morbidity and mortality (Van Marter et al., 1990; Kavvadia et al., 2000; Lundstrom et al., 2000), judicious use of fluid administration is warranted. On the other hand, combined relative and absolute hypovolemia is clearly a major etiologic factor contributing to neonatal shock in neonates with sepsis and/or in the postoperative period in patients undergoing major surgery. Indeed, early and aggressive fluid resuscitation of children and neonates with sepsis has been documented to decrease mortality (Han et al., 2003) and has been recommended by the American College of Critical Care Medicine (Brierley et al., 2009).

Further controversy has emerged concerning the type of fluid administered to preterm neonates with cardiovascular compromise. Most studies have shown that isotonic saline is as effective as 5% albumin in increasing the blood pressure (So et al., 1997; Oca et al., 2003). In addition, albumin may impair gas exchange and induce fluid shift from the intracellular compartment (Ernest et al., 1999) and is associated with increased mortality (Nadel et al., 1998). Therefore given the documented comparable efficacy of isotonic saline and albumin in the face of differences in cost and the suggested increased mortality and morbidity associated with albumin administration (Van Marter et al., 1990; Kavvadia et al., 2000; Lundstrom et al., 2000), isotonic saline has been the initial choice of treatment in the neonatal patient population. However, an RCT found that in hypotensive, mostly preterm neonates, albumin administration resulted in a greater likelihood of achieving normotension and decreased the subsequent use of vasopressors when compared with isotonic saline (Lynch et al., 2008). The findings of that study need to be replicated before the routine use of albumin can be considered as the initial treatment for neonatal cardiovascular compromise. Therefore unless evidence of serum or blood loss or hypoalbuminemia is present, volume support in hypotensive preterm and term infants is provided in the form of 10 to 20 mL of isotonic saline per kilogram (Seri, 2001; Noori and Seri, 2012). It is also important to note that, because of the unbalanced nature of isotonic saline, caution should be exercised with administration of large amounts in a short period, as this may worsen the metabolic acidosis (Mirza et al., 1999; Prough and Bidani, 1999).

Should the limited-volume administration be ineffective, pharmacologic cardiovascular support with a vasopressor-inotrope or an inotrope is recommended (Seri, 1995, 2001; Osborn et al., 2002; Kluckow, 2005; Seri and Noori, 2005; Noori and Seri, 2012). However, based on the recent findings of the aforementioned studies on the use of delayed cord clamping or cord milking, it is likely that once clinical practice changes as per the recommendations of the expert panels (Committee on Obstetric Practice, American College of Obstetricians and Gynecologists, 2012; Perlman et al., 2015), the need for volume administration in the immediate transitional period will decline.

If there is an identifiable volume loss, the type of fluid lost should be replaced. In cases of blood loss, transfusion with packed red blood cells after the initial crystalloid or colloid bolus or packed red blood cells suspended in fresh frozen plasma with a hematocrit around 55% may be used. In cases of increased transepidermal water losses, higher free water administration without an increase in sodium supplementation is indicated. When polyuria is present, the composition and volume of the replacement fluid may be

adjusted to the urinary sodium and free water losses. However, replacement of half of the excessive urinary losses with 0.45% saline will usually suffice.

Dopamine and Dobutamine

Dopamine treatment and dobutamine treatment were introduced in the management of neonatal hypotension in the early 1980s and mid-1980s, respectively, without appropriately designed randomized and blinded clinical trials. Thus as mentioned earlier, we have no clear evidence that the use of these sympathomimetic amines (or any other sympathomimetic amine) reduces neonatal mortality or morbidity. By examining the drugs' effect on neonatal myocardial contractility, systemic blood flow, and organ blood flow, a number of studies have extended their focus beyond the dopamine- and dobutamine-induced heart rate and blood pressure changes (Roze et al., 1993; Seri et al., 1998; Zhang et al., 1999; Lundstrom et al., 2000; Osborn et al., 2002; Seri et al., 2002; Pellicer et al., 2005; Noori et al., 2006a; Bouissou et al., 2008; Bravo et al., 2015). Some of the earlier studies, however, used left ventricular output to assess the impact of these medications on systemic blood flow even when shunting across fetal channels occurred (Roze et al., 1993; Zhang et al., 1999; Lundstrom et al., 2000). Therefore the conclusions drawn in these studies need to be carefully reevaluated (Kluckow and Seri, 2012).

Hemodynamic Effects of Dopamine

Dopamine, an endogenous catecholamine, is the sympathomimetic amine most frequently used in the treatment of hypotension in preterm infants (Seri, 1995; Stranak et al., 2014). It exerts its cardiovascular actions via the dose-dependent stimulation of the cardiovascular dopaminergic, α -adrenergic, β -adrenergic, and serotonergic receptors. In addition, by stimulating epithelial and peripheral neuronal dopaminergic and adrenergic receptors, the drug exerts significant renal and endocrine effects independently of its cardiovascular actions (Seri, 1995). Although dopamine affects all three major determinants of cardiovascular function (preload, myocardial contractility, and afterload), the drug-induced increases in myocardial contractility (Zhang et al., 1999; Lundstrom et al., 2000) and peripheral vascular resistance (afterload) (Roze et al., 1993; Zhang et al., 1999; Lundstrom et al., 2000) are the most important factors in increasing systemic blood pressure and improving the cardiovascular status.

The original dosage range recommendation of 2 to 20 μg dopamine per kilogram per minute was based on pharmacodynamic data obtained in adults without cardiovascular compromise. However, changes in cardiovascular adrenergic receptor expression caused by critical illness (Hausdorff et al., 1990) and relative or absolute adrenal insufficiency and immaturity (Watterberg and Scott, 1995; Watterberg, 2002), as well as the dysregulated production of local vasodilators during severe illness, decrease the sensitivity of the cardiovascular system to dopamine, resulting in the emergence of hypotension resistant to conventional doses of the drug (Ng et al., 2001; Seri et al., 2001; Ng et al., 2006; Noori et al., 2006a). Thus with the advancement of the disease process, increased doses of dopamine and other sympathomimetic amines may be needed to exert the same magnitude of cardiovascular response. Therefore dopamine administration should be tailored to the drug's pharmacodynamic effects in a given patient at the bedside rather than driven by the conventional dose recommendations based on data obtained in healthy adults. Indeed, although many neonatologists do not advance the dosage of dopamine beyond 20 $\mu\text{g}/\text{kg}$ per

minute, there is no evidence that, when required to normalize blood pressure, high-dose dopamine treatment with or without additional epinephrine administration has detrimental vasoconstrictive effects (Perez et al., 1986; Seri et al., 2001). However, there are no data available on changes in cardiac output and organ blood flow in response to high-dose catecholamine treatment in vasopressor-resistant neonatal shock, and close attention should be paid to signs of inappropriate vasoconstriction when this therapy is applied. Administration of low-dose hydrocortisone in the past decade has been shown to reduce the need for high-dose vasopressor administration in most patients (Ng et al., 2001; Seri et al., 2001; Noori et al., 2006a; Seri, 2006; Cole, 2008).

As hypotension and circulatory failure are most common in the first few postnatal days, a period in which significant shunting at the PDA level is often present in VLBW infants, assessment of the cardiovascular effects of vasopressors/inotropes by echocardiography is challenging. This is especially true with regard to estimation of the magnitude of PDA shunt. Therefore one needs to be cautious in interpreting these studies. With that caveat in mind, several studies suggest that dopamine does not worsen left-to-right PDA shunt. Rather, in hypotensive preterm neonates with a significant left-to-right shunt across the PDA, dopamine administration increased systemic blood pressure, pulmonary pressure, and SVC flow, used as a surrogate of systemic blood flow in these patients (Bouissou et al., 2008). Similarly, dopamine administration has not been associated with evidence of increased pulmonary vascular resistance and decreased right ventricular output in neonates without a significant left-to-right shunting across the PDA (Wardle et al., 1999; Clark et al., 2002). This finding suggests that when pulmonary blood flow is increased, vasoconstrictive mechanisms may be upregulated in the pulmonary circulation, resulting in more effective α -receptor-mediated, dopamine-induced pulmonary vasoconstriction. The findings of an earlier study demonstrating a variable pulmonary resistance response to dopamine in preterm neonates with a hemodynamically significant PDA support this notion (Liet et al., 2002).

The vasodilatory dopamine receptors are primarily expressed in renal, mesenteric, and coronary circulations (Seri, 1995). Dopamine has been shown to selectively decrease renal vascular resistance (Seri et al., 1998, 2002) and increase glomerular filtration rate (Seri et al., 1993) in preterm infants as early as the 23rd week of gestation. However, dopamine appears to decrease mesenteric vascular resistance in preterm infants only beyond the first postnatal day (Hentschel et al., 1995; Seri et al., 1998, 2002; Robel-Tillig et al., 2007), and the effect may be variable (Zhang et al., 1999). Similarly, there are some differences in the reported magnitude of the drug-induced increases in ventricular function, cardiac output, and systemic vascular resistance (Roze et al., 1993; Zhang et al., 1999; Lundstrom et al., 2000; Clark et al., 2002). These findings may be best explained by differences in intravascular volume status, gestational and postnatal age, developmentally regulated expression of cardiovascular adrenergic and dopaminergic receptors, and the severity of adrenergic receptor downregulation among different populations of critically ill infants studied. It is important to note that none of the studies found evidence for a direct effect of dopamine on CBF as long as blood pressure was in the autoregulatory range (Seri et al., 1998; Zhang et al., 1999; Lundstrom et al., 2000; Seri et al., 2002). Thus dopamine administration appears to be devoid of potentially harmful selective hemodynamic effects in the brain. As expected in hypotensive neonates, dopamine (and epinephrine) increases both blood pressure and CBF (Pellicer et al., 2005).

Hemodynamic Effects of Dobutamine

Unlike dopamine, dobutamine is a relatively cardioselective sympathomimetic amine with significant α -adrenoreceptor-mediated and β -adrenoreceptor-mediated direct inotropic effects and limited chronotropic actions (Ruffolo, 1987). Dobutamine administration is usually also associated with a variable decrease in total peripheral vascular resistance and, at least in adults, with improved coronary blood flow and myocardial oxygen delivery (Ruffolo, 1987). Furthermore, unlike dopamine, dobutamine increases myocardial contractility exclusively through the direct stimulation of myocardial adrenergic receptors. Because myocardial norepinephrine stores are immature and rapidly depleted in the newborn, and because dobutamine may decrease afterload, newborns with primary myocardial dysfunction and elevated peripheral vascular resistance are most likely to benefit from dobutamine treatment (Martinez et al., 1992; Osborn et al., 2002). However, dobutamine may offer little hemodynamic benefits if the primary underlying pathophysiology is not poor myocardial contractility. A recent placebo-controlled pilot trial showed dobutamine to have no effect on SVC flow (Bravo et al., 2015). Although addition of dobutamine to dopamine treatment in preterm infants with respiratory distress syndrome was effective in increasing blood pressure, it was associated with supranormal cardiac output states and low systemic vascular resistance (Lopez et al., 1997). Whether the benefits of supranormal cardiac output by providing adequate tissue oxygen delivery throughout the body outweigh the risks of sustained hypercontractility, potentially resulting in myocardial injury, remains to be investigated.

There are only few data available on direct renal, cerebral, or pulmonary hemodynamic effects of dobutamine in the newborn. A nonrandomized study comparing the effects of dopamine and dobutamine on blood pressure and mesenteric blood flow in preterm infants found that both drugs increased blood pressure and were equally effective in decreasing mesenteric vascular resistance (Hentschel et al., 1995). Because dobutamine does not stimulate the dopaminergic receptors, β -adrenoreceptor-induced selective vasodilation may be responsible for the observed mesenteric vasodilation in dobutamine-treated patients.

Dopamine Versus Dobutamine

Randomized studies have uniformly demonstrated that dopamine is more effective than dobutamine in increasing blood pressure in the preterm infant, and a metaanalysis of these studies confirmed that dopamine was more successful than dobutamine in treating hypotension, with fewer infants in the dopamine group facing treatment failure (Subdehar and Shaw, 2000). However, there was no difference in short-term adverse neurologic outcome between the two groups. In the absence of long-term outcome data, no firm recommendations can be made regarding the choice of drug in treating hypotension in preterm infants in the immediate postnatal period. In addition, no information was forthcoming on changes in systemic blood flow. However, with careful titration to a predetermined "optimum" hemodynamic effect, dopamine (and epinephrine) increased blood pressure and CBF in hypotensive VLBW neonates during the first postnatal day (Pellicer et al., 2005). Neurodevelopmental follow-up of patients enrolled in this study at 2 to 3 years of age did not reveal evidence of an independent vasopressor-inotrope-associated increase in morbidity (Pellicer et al., 2009; see earlier). Although the findings of this study provide some reassurance against the possibility of a dopamine (or epinephrine)-associated increase in neurodevelopmental

morbidity in VLBW neonates during the first postnatal day, the original study (Pellicer et al., 2005) was not sufficiently powered to put these concerns to rest.

As discussed earlier, because of the weak relationship between blood pressure and systemic blood flow in very preterm neonates during the immediate postnatal period, an increase in blood pressure does not necessarily guarantee that tissue perfusion has improved along with the blood pressure (Kluckow and Evans, 1996; Lopez et al., 1997; Kluckow and Evans, 2000a; Pladys et al., 1999; Kluckow and Seri, 2012). Although a recent study using laser Doppler measurements showed no evidence of peripheral vasoconstriction even with dopamine dosages greater than 10 $\mu\text{g/kg}$ per minute (Ishiguro et al., 2012), other studies have demonstrated impairment in systemic blood flow in a subset of patients despite improvements in blood pressure with higher doses of dopamine (Osborn et al., 2002). Therefore if there is evidence of peripheral vasoconstriction, especially in VLBW neonates during the first postnatal day, high-dose dopamine treatment should be attempted only if systemic blood flow can be monitored by functional echocardiography, NIRS, and/or other advanced perfusion monitoring techniques. However, in clinical practice these measures of blood flow monitoring, with the possible exception of NIRS, are not routinely available, and the neonatologist must rely on monitoring blood pressure and the indirect measures of cardiovascular function. If evidence of vasoconstriction is present with higher doses of dopamine (or epinephrine), the neonatologist should consider accepting blood pressures in the lower range for gestational age and postnatal age and decrease the dose of vasopressor-inotrope to levels where significant α -adrenoreceptor stimulation is less likely (Seri, 1995; Kluckow and Seri, 2012). In these cases and depending on the pathophysiology of the cardiovascular compromise, addition of dobutamine or milrinone should be considered, and the blood pressure should be maintained in the low-normal range. As systemic hypotension has been linked to poor long-term neurodevelopmental outcome in the VLBW neonatal patient population (Miall-Allen et al., 1987; Bada et al., 1990), careful consideration of the lowest acceptable perfusion pressure in the given patient is warranted. A combination of dobutamine or milrinone and low-dose dopamine may achieve the most important goals of treatment by maintaining blood pressure and systemic blood flow in acceptable ranges if monitoring of both cardiovascular parameters is possible. In most of these patients, physiologic glucocorticoid and mineralocorticoid replacement with hydrocortisone is likely to be effective, although the potential side effects of early hydrocortisone exposure in preterm neonates should be kept in mind (see later discussion) (Seri et al., 2001; Seri and Noori, 2005; Cole, 2008; Kluckow and Seri, 2012; Biniwale et al., 2013). In summary, as maintenance of appropriate perfusion pressure is necessary to ensure appropriate tissue oxygen delivery (systemic and organ blood flow) and because both hypotension and low systemic blood flow have been associated with impaired neurodevelopmental outcome, the primary goal of management of the hypotensive very preterm neonate should be the correction of both measures of cardiovascular function.

In hypotensive term and preterm neonates beyond the immediate postnatal period, where vasodilatory shock is the more likely presentation, dopamine (or epinephrine) administration in doses tailored to the cardiovascular response is warranted and appears to be beneficial (DiSessa et al., 1981; Martinez et al., 1992; Pellicer et al., 2005; Seri and Noori, 2005) unless evidence of primary myocardial dysfunction is present (Seri, 1995, 2001).

Epithelial and Neuroendocrine Effects

Independently of the aforementioned cardiovascular effects, dopamine exerts direct renal (Seri, 1995) and endocrine (Seri, 1995) actions in the newborn. Via its actions on renal blood flow and glomerular filtration rate as well as through its direct effects on sodium, phosphorus, and water transport processes and Na^+ , K^+ -ATPase activity in renal tubules, dopamine increases sodium, phosphorus, and free water excretion (Fig. 51.12) and may increase the hypoxic threshold of renal tubular cells during episodes of hypoperfusion and hypoxemia (Seri, 1995). Via its renal vascular and epithelial actions, dopamine also potentiates the diuretic effects of furosemide (Tulassay and Seri, 1986) and theophylline (Bell et al., 1998). Although dopamine has the theoretical potential to attenuate renal side effects of indomethacin, the data in the literature are contradictory (Seri, 1995). Differences in the level of maturity, disease severity, ductal shunting, intravascular volume

status, and indomethacin dose may be responsible for the conflicting results. Among its endocrine actions, the dopamine-induced decreases in plasma prolactin, thyrotropin, and growth hormone levels (Seri, 1995) may be of clinical importance. The decrease in plasma prolactin level may attenuate the preterm infant's propensity to edema formation but may also have a modulating effect on immune function (Seri, 1995). The inhibition of thyrotropin release necessitates the postponement of routine neonatal thyroid screening until after dopamine administration has been discontinued (Seri, 1995; Filippi et al., 2007). Dopamine, compared with dobutamine, decreases serum thyroid-stimulating hormone and thyroxine levels by approximately 70% to 80% and 50%, respectively (Filippi et al., 2007). As dobutamine does not stimulate dopaminergic receptors, its administration is devoid of neuroendocrine effects. The potential impact on long-term neurodevelopmental outcome and immunologic function of the drug-induced alterations in neuroendocrine function is not known in the preterm and term neonate.

• **Fig. 51.12** Effects of Dopamine Along the Nephron. Dopamine increases renal blood flow (RBF) by selective renal vasodilation and by increasing mesangial cell surface area and glomerular hydrostatic pressure via the preferential dilation of the afferent arteriole (black arrows). These changes result in increased single-nephron glomerular filtration rate (GFR). Administration of dopamine to normotensive preterm neonates results in increased sodium, phosphorus, and free water excretion (Seri, 1993, 1995). These effects are primarily caused by the drug-induced inhibition of Na^+ , K^+ -ATPase, Na^+ / H^+ exchanger, and the Na^+ /inorganic phosphate (Pi) cotransporter in the proximal tubule as well as inhibition of antidiuretic hormone (ADH)-induced phosphorylation of water channels in the collecting duct (Seri, 1995). The proposed resultant increase in bicarbonate excretion has not been documented in preterm infants. X in red represents inhibition of enzyme or transporter function. (Courtesy Kelly L, Seri I. Renal developmental physiology: relevance to clinical care. *NeoReviews*. 2008;9:e150–e161.)

Epinephrine, Norepinephrine, and Other Cardiovascular Agents and Hormones

Epinephrine

In an RCT, low to medium doses of epinephrine, when titrated to optimal hemodynamic response, were shown to increase blood pressure and CBF in hypotensive VLBW neonates (see earlier discussion) (Pellicer et al., 2005). Because of epinephrine's significant effect on glycogenolysis, its administration is associated with an increase in serum lactate levels independently of the drug's cardiovascular actions (Valverde et al., 2006). This effect should be kept in mind when one is following serum lactate levels to assess the changes in cardiovascular status due to epinephrine administration. Therefore the epinephrine-induced improvement in perfusion cannot be ascertained by the following of serum lactate levels alone, because these levels will likely increase independently of drug-induced improvement in the cardiovascular status.

It is not known whether there is a difference in the cardiovascular response and/or side effects of sympathomimetic amines with the combined use of epinephrine and dopamine compared with the use of increasing dosages of dopamine beyond 20 µg/kg per minute with or without dobutamine. In preliminary publications, no detrimental vasoconstrictive effects have been reported with the use of either high doses of epinephrine with or without dopamine or norepinephrine in sick neonates and children (Derleth, 1997; Campbell and Byrne, 1998; Seri and Evans, 1998). These findings are best explained by the downregulation of cardiovascular adrenergic receptors and thus the decreased cardiovascular sensitivity of critically ill preterm infants to catecholamines, necessitating escalation of sympathomimetic support. However, one must be extremely careful when escalating treatment with these potent vasopressors–inotropes to decrease the risk of unwarranted severe vasoconstriction and compromised tissue perfusion. As referred to earlier, with the appropriate use of low-dose hydrocortisone in patients with evidence of relative adrenal insufficiency (also see later), high-dose vasopressor support is rarely required.

Norepinephrine

Norepinephrine is the drug of choice for the treatment of septic (vasodilatory) shock in adult patients and is being increasingly used in children with septic shock (Lampin et al., 2012; Dellinger et al., 2013). However, because of a number of developmentally regulated factors, the pharmacokinetics and pharmacodynamics of norepinephrine are different in neonates. Unfortunately, few data are available on the effectiveness and safety of norepinephrine in the neonatal population (Oualha et al., 2014). Until very recently, findings on the cardiovascular effects of norepinephrine in neonates were published only in abstract form (Derleth, 1997). However, a more recent observational study in late preterm and term neonates with persistent pulmonary hypertension of the newborn (PPHN) treated with inhaled nitric oxide (iNO) who also had signs of circulatory failure found that medium doses of norepinephrine improved systemic and pulmonary cardiovascular function by decreasing the pulmonary artery to aortic pressure gradient and improving cardiac performance (Tourneux et al., 2008a). Another observational study found improvement in blood pressure, urine output, and lactic acidosis in term infants with refractory hypotension unresponsive to conventional treatment (Tourneux et al., 2008b). Although these findings are encouraging, the routine use of norepinephrine in the treatment of neonates with PPHN and cardiovascular compromise requires further confirmation.

Milrinone

There are few data available on the cardiovascular effects of milrinone, a phosphodiesterase 3 inhibitor in the neonatal patient population (Samiee-Zafarghandy et al., 2015). It has been widely used to reduce afterload in neonates with congenital heart disease with low cardiac output syndrome after surgery (Hoffman et al., 2003). With regard to its use in term infants without congenital heart disease, milrinone administration has been shown in a small case series to improve the oxygenation index without compromising systemic blood pressure when given to term neonates with PPHN treated with iNO during the first 2 days postnatally (McNamara et al., 2006). Another small retrospective study found improvement in indices of cardiac function about 24 hours after initiation of milrinone treatment in late preterm and term infants with pulmonary hypertension treated with iNO (James et al., 2015). The preferential effect of milrinone on the pulmonary circulation in neonates with PPHN treated with iNO may be due to the upregulation of phosphodiesterase 3 in pulmonary vessels in response to iNO administration (Chen et al., 2009). It is unclear if milrinone has a positive inotropic effect in neonates (Barrington and Dempsey, 2006). A retrospective study of 1446 neonates exposed to milrinone found that 42% of the neonates had adverse effects attributed to the drug administration (Samiee-Zafarghandy et al., 2015). Arterial hypotension prompting vasopressor–inotrope administration and thrombocytopenia were the most frequently noted adverse effects.

A randomized placebo-controlled blinded clinical trial investigated whether the use of milrinone would minimize or prevent the suspected increase in systemic vascular resistance and the associated systemic hypoperfusion in VLBW infants during the first postnatal day (Paradis et al., 2009). However, there was no reduction in the incidence of low SVC flow used as a surrogate of systemic blood flow in patients treated with milrinone compared with the placebo group. These findings may be explained, at least in part, by the little-appreciated complexity of the pathophysiology of cardiovascular compromise in the very preterm neonate after delivery (Wu et al., 2016). They further suggest that systemic and cerebral hypoperfusion and reperfusion in this patient population may not solely occur because of the inability of the immature myocardium to pump against the sudden postnatal increase in systemic vascular resistance (Noori et al., 2009, 2014a).

Vasopressin

The primary cardiovascular effect of vasopressin in the systemic circulation is vasoconstriction. However, in the pulmonary circulation, low doses of vasopressin have been shown to induce vasodilation in adults. In neonates with pulmonary hypertension, including patients with congenital diaphragmatic hernia, several case series have also reported improvement in oxygenation and decrease in pulmonary pressure following low-dose vasopressin administration (Radicioni et al., 2012; Acker et al., 2014; Mohamed et al., 2014). However, as expression of vasopressin receptors is developmentally regulated, it is unclear if vasopressin truly induces selective pulmonary vasodilation in the neonatal population (Enomoto et al., 2014).

Its systemic pharmacodynamic profile makes vasopressin a good candidate for treatment of circulatory failure when the underlying pathophysiology is primarily that of vasodilation such as in septic shock without myocardial dysfunction or systemic inflammatory response following cardiac surgery. However, there are only case series reporting improvement in systemic hemodynamics in preterm and term infants with refractory hypotension or septic shock (Meyer

et al., 2006a, 2006b; Bidegain et al., 2010; Ikegami et al., 2010). A recent randomized pilot study compared vasopressin with dopamine as the first line of treatment in hypotensive preterm infants (Rios and Kaiser, 2015). It found that vasopressin resulted in similar improvement in blood pressure and urine output compared with dopamine. In addition, the vasopressin group had less tachycardia. Yet, more data on the safety and efficacy of vasopressin are needed before it can be introduced in the routine clinical care of critically ill neonates with vasodilatory shock (Shivanna et al., 2013).

Steroid Administration

Steroid Administration as Primary or Rescue Treatment

A small RCT showed that low-dose hydrocortisone improves blood pressure but is less effective than dopamine in hypotensive preterm infants (Bouchier and Weston, 1997). Given the concerns about adverse long-term effects of steroids (primarily dexamethasone) and inadequate data on their efficacy, steroids are not recommended as the first-line treatment of hypotensive infants (Ibrahim et al., 2011).

For rescue treatment, there is now overwhelming evidence provided by descriptive studies (Helbock et al., 1993; Ng et al., 2001; Seri et al., 2001; Heckmann and Pohlandt, 2002; Noori et al., 2006a) and confirmed by randomized blinded prospective trials (Bouchier and Weston, 1997; Gaissmaier and Pohlandt, 1999; Watterberg et al., 1999; Efrid et al., 2005; Ng et al., 2006) that brief steroid treatment stabilizes the cardiovascular status and decreases the need for vasopressor–inotropic support in the critically ill preterm and term newborn with vasopressor-resistant hypotension. Because there is overwhelming evidence that early and/or medium-to-high cumulative doses of dexamethasone have detrimental effects on the developing brain (O’Shea et al., 1999; Shinwell et al., 2000; Halliday et al., 2003; Baud, 2004; Yeh et al., 2004; Hitzert et al., 2012), and because in addition to glucocorticoids, mineralocorticoids also have significant effects on the cardiovascular system (Wehling et al., 1995; Wehling, 1997), even low-dose dexamethasone administration to treat vasopressor-resistant hypotension has fallen by the wayside in recent years. This section therefore addresses only the actions, side effects, recommended doses, and remaining clinically relevant concerns of hydrocortisone administration to treat vasopressor-resistant hypotension in the critically ill neonate. It is of note that the available evidence for the effectiveness of low-dose hydrocortisone to increase blood pressure and decrease vasopressor–inotrope requirement in the preterm neonate is so strong that it would take 74 and 188 future studies, respectively, demonstrating no effect of hydrocortisone on blood pressure increase and on the decrease in vasopressor requirement to eliminate the statistical power of the present findings (Higgins et al., 2010).

Rationale for Hydrocortisone Treatment

Because in most patients and after some time cardiovascular stability will be achieved by the use of vasopressors–inotropes and/or inotropes alone, it is important to understand the rationale for hydrocortisone administration, especially because the drug has its own side effects (see later discussion).

First, it is widely accepted although not proven that the sooner one normalizes blood pressure and systemic perfusion, especially in the VLBW neonate during the immediate postnatal period, the better the outcome. However, because normal blood pressure in the first 24 hours may not guarantee normal cerebral perfusion (see earlier discussion) and because an association but not causation

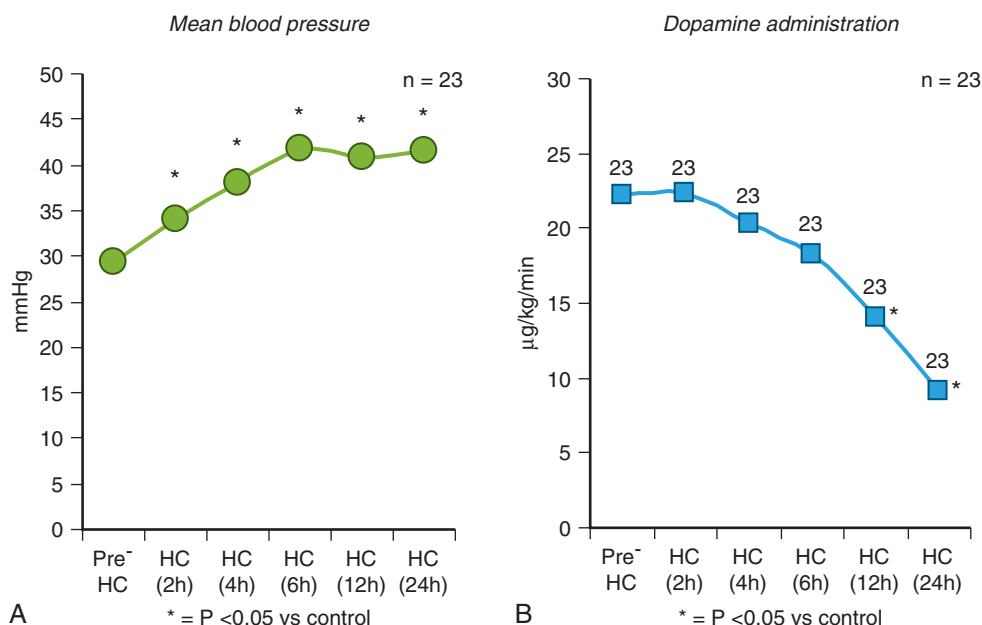

has been documented between hypotension and adverse outcomes, stabilization of the cardiovascular status with little blood pressure fluctuation remains an intuitively desirable goal but one without much direct evidence to support it.

Second, and more importantly, hydrocortisone specifically addresses the underlying cause of the cardiovascular instability in most critically ill neonates and thus is the logical choice of treatment. Indeed, developmental endocrinology and cardiovascular physiology findings as well as recent clinical data support a role for hydrocortisone use in critically ill hypotensive neonates, especially in VLBW neonates (Biniwale et al., 2013). In critical illness, desensitization of the cardiovascular system to catecholamines occurs through the downregulation of cardiovascular adrenergic receptors and second messenger systems (Hausdorff et al., 1990). This process is attenuated or prevented by the regulatory actions of glucocorticoids on the expression of cardiovascular adrenergic receptors and second messenger systems (Hausdorff et al., 1990). In addition, the direct increase in myocardial and vascular smooth muscle cell contractility induced by mineralocorticoids also plays an effective role (Wehling et al., 1995; Wehling, 1997). Furthermore, corticosteroids contribute to the maintenance of capillary integrity, inhibit catecholamine metabolism and reuptake of norepinephrine into sympathetic nerve endings, increase the expression of angiotensin type 2 receptors in the myocardium, and inhibit prostacyclin production and the induction of inducible nitric oxide synthase. Each of these actions of corticosteroids aids in maintaining the sensitivity of the cardiovascular system to catecholamines in response to acute stress or critical illness.

Third, because of the role of glucocorticoids in the physiologic regulation of adrenergic receptor expression (Hausdorff et al., 1990), the emergence of vasopressor resistance in itself may indicate a state of relative adrenal insufficiency. The findings of several recent studies indicate that critically ill preterm and term infants are likely to develop relative adrenal insufficiency because of their immature adrenal function (Watterberg and Scott, 1995; Watterberg, 2002; Ng et al., 2004) and hypothalamopituitary axis (Fernandez et al., 2008; Fernandez and Watterberg, 2009), respectively. It is important to emphasize that, on the basis of these findings, it appears that in the VLBW neonate adrenal unresponsiveness to endogenous or exogenous adrenocorticotrophic hormone (Watterberg, 2002; Ng et al., 2004) and in the late preterm and term neonate unresponsiveness of the hypothalamopituitary axis to stress (Fernandez et al., 2008; Fernandez and Watterberg, 2009) are the primary causes for the development of relative adrenal insufficiency. Thus these patients have limited capacity to mount sufficient adaptive increases in endogenous steroid production to prevent the development of cardiovascular adrenergic receptor downregulation and desensitization of the cardiovascular system to catecholamines during their illness. Therefore in critically ill preterm and term infants with vasopressor-resistant hypotension, steroid administration also serves as hormone substitution therapy.

Clinical Applications of Hydrocortisone

As mentioned earlier, use of hydrocortisone as primary treatment in hypotensive preterm infants is not recommended. On the other hand, although long-term effects need to be further studied (see later), there is justification for the use of hydrocortisone as a secondary rescue treatment. Available evidence indicates that hydrocortisone in preterm and term infants with vasopressor-resistant hypotension increases blood pressure within 2 hours of the initiation of treatment (nongenomic effects) and decreases vasopressor requirement within 8 to 12 hours of the first dose of the drug (genomic effects)

• **Fig. 51.13** Effect of Hydrocortisone on Mean Blood Pressure and the Dose of Dopamine During the First 24 Hours of Hydrocortisone Treatment in 23 Preterm Neonates With Vasopressor-Resistant Shock. (A) Mean blood pressure and (B) mean dopamine requirement during the 12 hours before and the first 24 hours after the first dose of hydrocortisone (HC). Before HC administration, blood pressure remained low (A), despite significantly increased dopamine doses (B; asterisk $P < .05$ vs the baseline [0 hour]). However, mean blood pressure increased significantly by 2 hours after the first dose of HC (A; asterisk $P < .05$ vs the baseline [0 hour]) and continued to rise until 6 hours of HC therapy, remaining stable thereafter (A; asterisk $P < .05$ vs the baseline [0 hour]; $P < .05$ vs HC therapy [2 hours]). In addition, the dose of dopamine significantly decreased by 12 and 24 hours of HC therapy (B; asterisk $P < .05$ vs the baseline [0 hour]). (Courtesy Seri I, Tan R, Evans J. Cardiovascular effects of hydrocortisone in preterm neonates with pressor resistant hypotension. *Pediatrics*. 2001;107:1070–1074.)

(Fig. 51.13) (Seri et al., 2001; Ng et al., 2006; Noori et al., 2006a). A study in preterm infants without a PDA documented that the hydrocortisone-induced improvement in blood pressure is associated with improvements in all aspects of cardiovascular function, including stroke volume and tissue perfusion (Fig. 51.14) (Noori et al., 2006b). It is important to note that because of the decreased clearance of hydrocortisone, lower and less frequent dosing are sufficient to induce the desired hemodynamic effects in preterm and term infants (Noori et al., 2006b; Vezina et al., 2014; Waterberg, 2016).

Short-Term Side Effects

With regard to the side effects of early or late low-dose hydrocortisone administration, the potential occurrence of short-term and long-term sequelae is of great interest. For the short-term side effects, it has been repeatedly documented that coexposure of preterm neonates to indomethacin and hydrocortisone during the first postnatal week significantly increases the risk of spontaneous gastrointestinal (mostly ileal) perforations (Waterberg et al., 2004; Peltoniemi et al., 2005). This serious untoward effect curtails the use of hydrocortisone in the VLBW neonate during the first postnatal week, the very patient population in whom vasopressor-resistant hypotension and relative adrenal insufficiency are most prevalent during the immediate postnatal period. The preliminary findings of one of these studies might suggest that VLBW neonates with low baseline serum cortisol levels may be at less risk of developing ileal perforations when treated with low-dose hydrocortisone and a cyclooxygenase inhibitor during the first few postnatal days (Peltoniemi et al., 2005). However, this observation

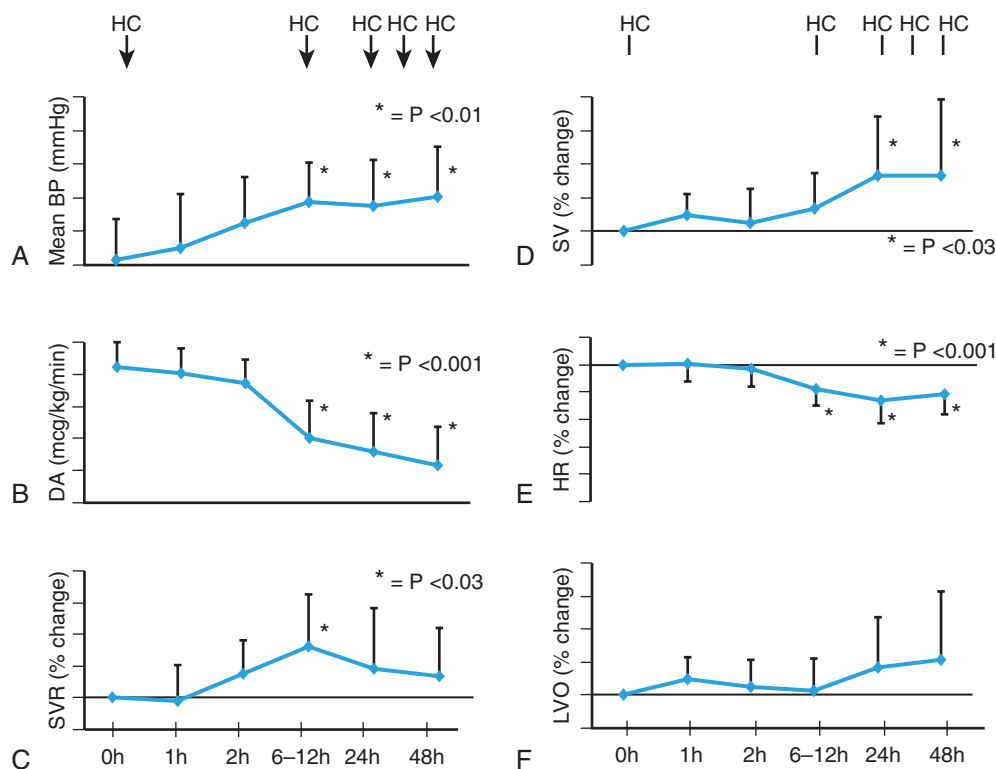

needs to be confirmed before it can be used to predict the likelihood of spontaneous intestinal perforation based on the basal serum cortisol level alone. For the other short-term side effects of hydrocortisone, one earlier study found an increase in the incidence of systemic fungal infections (Botas et al., 1995). However, none of the other studies have documented a significant increase in bacterial or fungal infections in neonates. Finally, hydrocortisone administration–associated transient hyperglycemia and hypertension have been reported in a few cases in the literature.

Long-Term Side Effects

Regarding the potential long-term side effects, the most pressing question is whether low to moderate doses of hydrocortisone interfere with neurodevelopment, especially in preterm neonates.

A placebo-controlled trial showed that early, low-dose hydrocortisone treatment for the prevention of bronchopulmonary dysplasia used in the first 10 days postnatally was not associated with an increased incidence of cerebral palsy (Waterberg et al., 2004) and might have been associated with evidence of improvement in some measures of neurodevelopmental outcome at 18 to 22 months' corrected age when compared with controls (Waterberg et al., 2007).

With regard to the use of higher cumulative doses of hydrocortisone for the treatment of evolving bronchopulmonary dysplasia outside the immediate transitional period, the results of a study examining structural and functional brain development at an age of 8 years suggest that hydrocortisone, used for the treatment of bronchopulmonary dysplasia in ventilator-dependent preterm

• **Fig. 51.14** Effect of Hydrocortisone on Systemic Hemodynamics and Dopamine Requirement During the First 48 Hours of Hydrocortisone Treatment in 15 Preterm Neonates With Vasopressor-Resistant Shock. Changes in mean blood pressure (BP; A) and dopamine dosage (DA; B) and percentage changes relative to the baseline (0 hours) in systemic vascular resistance (SVR; C), stroke volume (SV; D), heart rate (HR; E), and left ventricular output (LVO; F) at 1 hour, 2 hours, 6 to 12 hours, 24 hours, and 48 hours after the first dose of hydrocortisone (HC). Arrows indicate the approximate timing of hydrocortisone doses. Significant *P* values for pairwise comparisons versus the baseline (0 hour) with adjustment for multiple comparisons (Bonferroni) are shown. See the text for details. (Courtesy Noori S, Friedlich P, Wong P, et al. Hemodynamic changes following low-dose hydrocortisone administration in vasopressor-treated neonates. *Pediatrics*. 2006;118:1456–1466.)

neonates at a median age of 18 days and at cumulative doses exceeding 50 mg, does not interfere with brain development (Lodygensky et al., 2005). In addition, case-control studies have shown no difference in cerebral and cerebellar tissue volumes on MRI at term equivalent in preterm infants treated with hydrocortisone for bronchopulmonary dysplasia compared with the controls (Benders et al., 2009; Kersbergen et al., 2013). A small RCT of hydrocortisone with a cumulative dose of 17 mg/kg started moderately early (at 10–21 days) also showed no difference in regional brain volume at term equivalent compared with the controls (Parikh et al., 2013). However, one small RCT found a trend for a higher rate of neurodevelopmental impairment in the hydrocortisone group compared with the placebo group (61% vs 39%) at school age (Peltoniemi et al., 2016).

Although overall hydrocortisone appears to be safer than dexamethasone, the lack of power of the RCTs and the retrospective nature of the observational or retrospective studies warrant caution before the use of early or late and low-dose to medium-dose hydrocortisone can be declared safe in preterm neonates, at least from a neurodevelopmental standpoint.

Supportive Measures

Maintenance of a normal intravascular volume, arterial pH, and serum ionized calcium concentration is necessary for the optimum

cardiovascular response to catecholamines. A previous study found that metabolic acidosis (pH < 7.25) may compromise myocardial function in the preterm infant (Fanconi et al., 1993), and so it has been recommended that the arterial pH be maintained in or above this range in cases of acidosis with a significant metabolic component. On the other hand, respiratory acidosis has been shown to have no to minimal effect on cardiac function, myocardial contractility, and systemic vascular resistance in hemodynamically stable, preterm infants during the transitional period (Noori et al., 2013). However, and as discussed earlier, respiratory acidosis has significant effects on cerebral hemodynamics, and its cardiovascular effects in neonates receiving cardiovascular support are not known (see *Respiratory Support and Hemodynamics*). Therefore more data are needed to define the optimal pH and acid-base status in preterm and term infants receiving respiratory support. Administration of sodium bicarbonate (Fanconi et al., 1993) or, in neonates with severe combined respiratory and metabolic acidosis, the administration of tromethamine rapidly improves arterial pH. However, the efficacy and potential short-term and long-term adverse effects of such supportive treatment measures have not been studied in the neonatal patient population, and there is indeed very little evidence that bicarbonate administration for management of metabolic acidosis caused by tissue hypoperfusion is beneficial (Aschner and Poland, 2008). Finally, although positive pressure ventilation may raise pleural pressure and has the potential to

reduce venous return, it may also reduce left ventricular afterload by reducing transmural pressure and decreasing or eliminating the work of breathing. Decreasing or eliminating the work of breathing will also decrease or eliminate the concomitant cardiac output diverted to respiratory muscles. Therefore the net hemodynamic effect of positive pressure ventilation is improved systemic oxygen delivery independent of any potential improvement in pulmonary gas exchange. On the other hand, excessive positive pressure and lung hyperexpansion are associated with decreases in pulmonary and systemic blood flow.

In summary, sustained stabilization of the cardiovascular status with provision of appropriate blood pressure, cardiac output, and tissue perfusion and oxygenation remains a difficult task in most of the critically ill hypotensive neonates. Treatment of these patients requires the ability to continuously monitor the most important measures of cardiovascular function (blood pressure, systemic blood flow, and tissue oxygenation), a thorough understanding of the pathogenesis and pathophysiology of neonatal shock, and a thorough understanding of the mechanisms of action, pharmacodynamics, and potential side effects of sympathomimetic amines and other medications used in the management of neonatal shock.

Persistent Pulmonary Hypertension

ROBIN H. STEINHORN AND STEVEN H. ABMAN

KEY POINTS

- Persistent pulmonary hypertension of the newborn (PPHN) can occur with parenchymal disease, with lung hypoplasia, or without associated lung disease (*idiopathic*) and has an incidence of 0.2% in term infants and up to 2% in preterm infants.
- Maternal factors such as diabetes, high body mass index, smoking, use of selective serotonin receptor inhibitors or nonsteroidal antiinflammatory drugs, and cesarean delivery increase the risk of PPHN. Postnatal factors include perinatal asphyxia, hyperoxia, hypoxia, infection, and lung inflammation.
- Medical management of PPHN requires careful optimization of right and left ventricular function. Lung recruitment strategies should be applied in patients with parenchymal lung disease.
- Inhaled nitric oxide improves oxygenation and reduces the need for extracorporeal membrane oxygenation support in term and near-term infants with PPHN.
- Extracorporeal membrane oxygenation support is indicated for term and near-term neonates with severe pulmonary hypertension and/or hypoxemia that is refractory to inhaled nitric oxide therapy and optimization of respiratory and cardiac function.
- Chronic pulmonary hypertension occurs in a subset of infants with congenital diaphragmatic hernia and bronchopulmonary dysplasia and increases morbidity and mortality.
- Infants who survive moderate to severe PPHN are at a high risk of neurodevelopmental impairment and should undergo neuroimaging and neurodevelopmental follow-up.

Neonatal respiratory failure affects 2% of all live births and contributes to more than one-third of all neonatal mortality (Angus et al., 2001). Persistent pulmonary hypertension of the newborn (PPHN) is a frequent complication of neonatal respiratory disease and is defined as the failure to achieve or sustain the normal decrease in pulmonary vascular resistance (PVR) at birth. PPHN can produce severe respiratory distress and hypoxemia because of severe pulmonary vascular disease remodeling (Fig. 52.1) in term and near-term infants. Death and morbidity are common (Kinsella and Abman, 1995; Walsh-Sukys et al., 2000), including chronic lung disease and neurodevelopmental sequelae. While PPHN can be idiopathic, it is more commonly associated with a wide array of lung diseases, including meconium aspiration syndrome, perinatal asphyxia, congenital diaphragmatic hernia (CDH), pneumonia, and respiratory distress

syndrome. PPHN can also occur in premature infants with early respiratory distress, particularly after prolonged rupture of membranes and pulmonary hypoplasia (Aikio et al., 2012; de Waal and Kluckow, 2015). Chronic pulmonary hypertension is associated with lung diseases such as bronchopulmonary dysplasia (BPD) and CDH and is a common complication of congenital heart disease. This chapter will review the pathophysiology of PPHN, clinical treatment of newborns with severe disease, and outcome data.

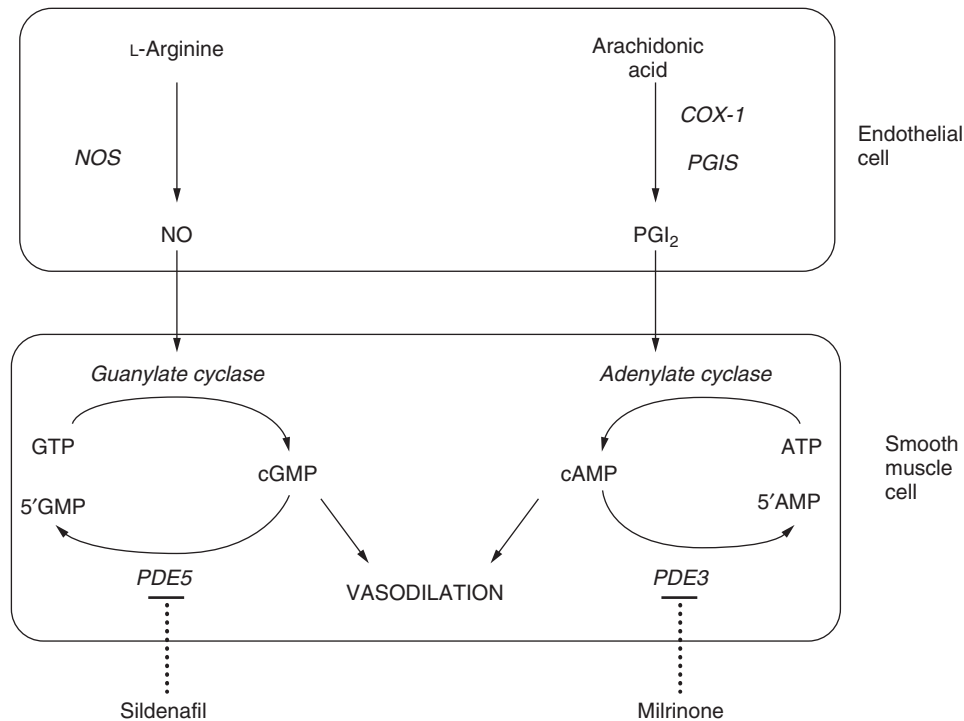

Normal Fetal Pulmonary Vascular Development and Transition

During fetal life, placental vascular resistance is low and PVR is high. This state of physiologic pulmonary hypertension is needed to maintain the patterns of blood flow that support gas exchange by the placenta. In the human fetus, only 10%–20% of the combined ventricular output is directed to the pulmonary vascular bed, and most of the right ventricular output crosses the ductus arteriosus to the descending aorta. During late gestation there is a marked increase in cross-sectional area of the pulmonary vascular bed. During this same timeframe, pulmonary vessels become more sensitive to vasoconstrictive mediators, such as endothelin and hypoxia, resulting in active pulmonary vasoconstriction and a net increase in PVR. The dilatory response to increased oxygen also emerges in late gestation. Pulmonary vasoconstriction is also promoted by low basal production of vasodilators such as prostacyclin and nitric oxide (NO) and low activity of pulmonary arterial soluble guanylate cyclase.

At birth, a rapid and dramatic decrease in PVR redirects half of the combined ventricular output to the lung and increases pulmonary blood flow by 8-fold to 10-fold. Increased pulmonary blood flow increases pulmonary venous return and left atrial pressure, promoting functional closure of the one-way valve of the foramen ovale. Clamping of the umbilical cord removes the low-resistance placental circulation, increasing systemic vascular resistance. The largest drop in PVR and pulmonary arterial pressure occurs shortly after birth, although both will continue to drop during the first few months of life until the low levels that are typical of the adult circulation are reached. As PVR falls below systemic levels, blood flow through the patent ductus arteriosus reverses. During the first several hours of life the ductus arteriosus functionally closes, largely in response to the increased oxygen tension of the newborn. This

• **Fig. 52.1** Histologic appearance of a pulmonary vessel from an infant with fatal persistent pulmonary hypertension of the newborn (PPHN) illustrating the dramatic remodeling that can be associated with severe PPHN.

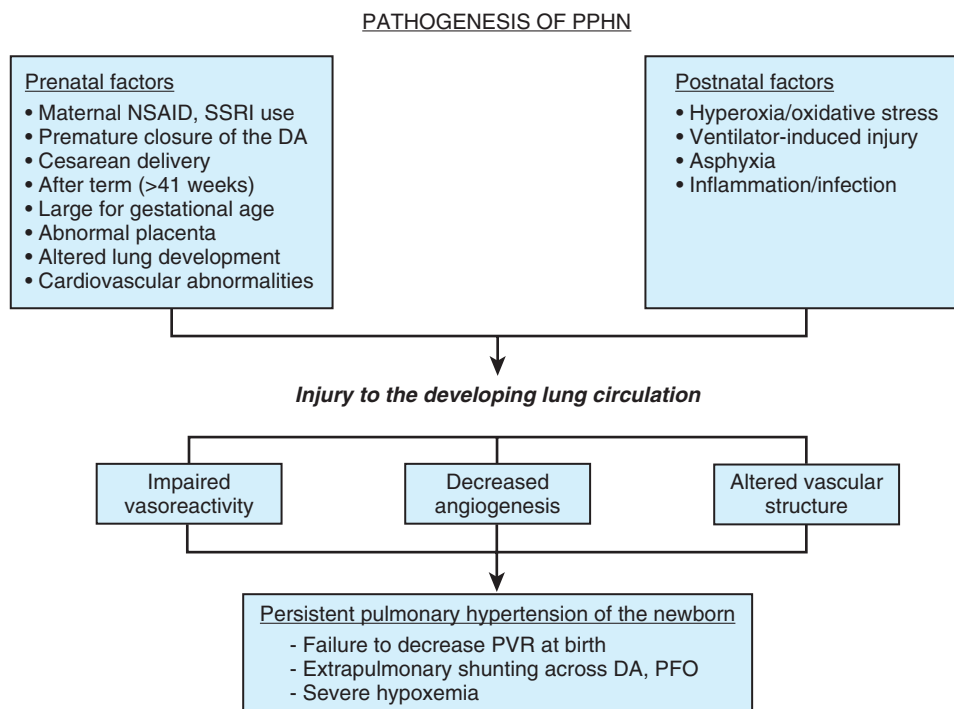

• **Fig. 52.2** Nitric oxide (NO) and prostacyclin (PGI₂) signaling pathways that regulate pulmonary vascular tone in the developing lung. ATP, Adenosine triphosphate; cAMP, cyclic AMP; cGMP, cyclic GMP; COX-1, cyclooxygenase 1; GTP, guanosine triphosphate; NOS, nitric oxide synthase; PDE3, phosphodiesterase 3; PDE5, phosphodiesterase 5; PGIS, prostacyclin synthase.

effectively separates the pulmonary and systemic circulations and establishes the normal postnatal circulatory pattern.

These transitional changes in the pulmonary vasculature are initiated by ventilation of the lung and an increase in oxygen tension and are mediated by several vasoactive compounds. The fetus prepares for the transition late in gestation by increasing pulmonary vascular expression of NO synthases and soluble guanylate cyclase (Fig. 52.2). Pulmonary endothelial NO production increases markedly at the time of birth, partly as a response to

increased oxygen tension and shear stress. NO exerts its action through soluble guanylate cyclase, an enzyme whose level peaks in late gestation (Bloch et al., 1997) and increases the levels of cyclic guanosine monophosphate (cGMP), a central mediator responsible for vascular relaxation. Phosphodiesterase 5 (PDE5) catalyzes the breakdown of cGMP and, similarly to soluble guanylate cyclase, exhibits peak expression and activity in the immediate newborn period (Hanson et al., 1998; Sanchez et al., 1998). The arachidonic acid–prostacyclin pathway also plays a significant role

• **Fig. 52.3** Pathogenesis of persistent pulmonary hypertension of the newborn (PPHN). DA, Ductus arteriosus; NSAID, nonsteroidal antiinflammatory drug; PFO, patent foramen ovale; PVR, pulmonary vascular resistance; SSRI, selective serotonin receptor inhibitor.

in the transition at birth (see Fig. 52.1). The enzyme cyclooxygenase acts on arachidonic acid to produce prostaglandin endoperoxides. Prostaglandins activate adenylate cyclase to increase cyclic adenosine monophosphate (cAMP) concentrations in vascular smooth muscle cells, which, similarly to increases in cGMP concentrations, leads to vasorelaxation. Phosphodiesterase 3A catalyzes the breakdown of cAMP.

Several events can disrupt the perinatal transition and contribute to the pathogenesis of PPHN (Fig. 52.3). Birth by elective cesarean delivery delays the decrease in pulmonary arterial pressure and increases the risk of PPHN (Makihara et al., 1993), and delivery before 39 weeks' gestation likely amplifies this effect. When compared with matched controls, infants with PPHN are more likely to have been born by cesarean delivery, and elevated risk of PPHN is also associated with maternal diabetes, asthma, and high body mass index (Hernandez-Diaz et al., 2007; Wilson et al., 2011). Perinatal asphyxia modifies the perinatal adaptation through a number of mechanisms that delay the fall in PVR and increase the risk of PPHN (Lapointe and Barrington, 2011), such as fetal hypoxemia, ischemia, acidosis, meconium aspiration, and ventricular dysfunction. Acute asphyxia is associated with reversible pulmonary vasoconstriction, but chronic in utero asphyxia can also induce vascular remodeling (Murphy et al., 1984). The adoption of therapeutic hypothermia for management of perinatal asphyxia raised many questions about its capacity to increase the risk of PPHN in asphyxiated infants. Deep levels of hypothermia (to 30°C–32°C) increased mean pulmonary arterial pressure in neonatal lambs (Toubas et al., 1978) and have been associated with an increased use of extracorporeal membrane oxygenation (ECMO) and inhaled nitric oxide (iNO) use in human studies. Furthermore, hypothermia shifts the oxygen dissociation curve to the left and decreases PaO₂ at a given peripheral oxygen saturation (SpO₂). However, pooled analysis of randomized trials of standard

hypothermia (33.5°C) has not shown an increased incidence of PPHN (25% vs 20%) in treated infants (Thoresen, 2011).

Pathophysiology of Persistent Pulmonary Hypertension of the Newborn

Failure of the normal cardiopulmonary transition after birth results in PPHN. The first reports of PPHN described term newborns with profound hypoxemia who lacked radiographic evidence of parenchymal lung disease and echocardiographic evidence of structural cardiac disease (Gersony et al., 1969; Levin et al., 1976). In these patients, hypoxemia was caused by marked elevations of PVR leading to right-to-left extrapulmonary shunting of blood across the patent ductus arteriosus or patent foramen ovale. Because of the persistence of high PVR and blood flow through these “fetal shunts,” the term *persistent fetal circulation* was originally used to describe these findings.

Consequently, it was recognized that these physiologic patterns can complicate the clinical course of term or preterm neonates with diverse causes of hypoxemic respiratory failure. As a result, the term *persistent pulmonary hypertension of the newborn* now denotes a syndrome characterized by common pathophysiologic features, including sustained elevation of PVR and hypoxemia due to right-to-left extrapulmonary shunting of blood flow across the ductus arteriosus or foramen ovale. These physiologic findings may be found in association with a wide range of cardiopulmonary disorders, such as meconium aspiration, sepsis, pneumonia, asphyxia, CDH, and respiratory distress syndrome. The term is often used interchangeably with *hypoxemic respiratory failure* although the term *persistent pulmonary hypertension of the newborn* should be reserved to describe neonates in whom extrapulmonary shunting contributes to hypoxemia and impaired cardiopulmonary function.

Most studies suggest an overall incidence for PPHN of 1.9 in 1000 live births or an estimated 7400 cases per year in the United States, although these rates differ widely from hospital to hospital (Walsh-Sukys et al., 2000; Huybrechts et al., 2015).

The 2013 Nice classification of pulmonary hypertension was expanded to capture the range of pediatric and neonatal disease (Ivy et al., 2013). Because of its specific anatomic and physiologic characteristics, PPHN was assigned a separate subcategory in group 1 (pulmonary arterial hypertension). In group 3 pulmonary hypertension (pulmonary hypertension due to lung disease or hypoxia), developmental lung diseases are specifically listed because of the important role that abnormal lung vascular growth plays in the pathogenesis of impaired lung development and pulmonary hypertension. CDH, BPD, and several other developmental lung disorders, such as surfactant protein deficiencies and alveolar capillary dysplasia, are now understood to be important causes of pulmonary hypertension in infants.

PPHN is commonly described according to its primary cause. Idiopathic PPHN is the least common, occurring in about 10% of cases. It refers to the absence of parenchymal lung disease to explain elevated pulmonary arterial pressure and implies intrauterine pulmonary vascular remodeling. However, PPHN is usually associated with other acute respiratory conditions, such as meconium aspiration syndrome, respiratory distress syndrome, or pneumonia, and is referred to as *secondary PPHN*. The hypoplastic vasculature, as seen in CDH, is associated with underdevelopment of the pulmonary vasculature and parenchyma and often leads to chronic pulmonary vascular disease. In many cases it can be more difficult to separate chronic intrauterine remodeling from acute pulmonary vasoconstriction due to parenchymal lung disease. For example, neonates with meconium aspiration often have clinical evidence of parenchymal disease and altered vasoreactivity, but excessive muscularization from intrauterine vascular remodeling is often found at autopsy.

Based on the significant remodeling found in lethal cases of PPHN, intrauterine events were presumed to affect pulmonary vascular growth, reactivity, and structure (Gegge and Reid, 1984; see Fig. 52.1). Pulmonary vascular development can be disrupted by environmental, placental, toxic, or other influences (see Fig. 52.3). Case-control surveillance studies indicate that maternal risk factors of black or Asian maternal race, elevated body mass index ($>27 \text{ kg/m}^2$), diabetes, and asthma predict a higher risk of PPHN. Neonatal risk factors include male sex, large for gestational age infants, birth by cesarean delivery, and delivery before 37 weeks' gestation or after 41 weeks' gestation (Hernandez-Diaz et al., 2007).

Recent animal and epidemiologic studies also suggest that maternal exposures can alter fetal pulmonary vascular development and function. There are strong associations between PPHN and maternal smoking, and two classes of maternal medications, nonsteroidal antiinflammatory drugs and selective serotonin receptor inhibitors, have also been implicated. Exposure to nonsteroidal antiinflammatory drugs such as aspirin or ibuprofen during the third trimester can cause constriction of the fetal ductus arteriosus, which in turn can trigger pulmonary vascular remodeling and PPHN. Based on the findings of a recent epidemiologic study, the relationship is complex and may be dependent on the specific agent and the timing of exposure (Van Marter et al., 2013), although aspirin use during late pregnancy remains a consistent risk factor for PPHN. Use of selective serotonin receptor inhibitors during the last half of pregnancy has been associated with an increased incidence of PPHN in several population studies, although the severity of PPHN has not been well described, and other studies

have not found this association (Kieler et al., 2012; Grigoriadis et al., 2014; Huybrechts et al., 2015). Maternal depression is a risk factor for adverse pregnancy outcomes, so maternal physical and psychologic well-being remain the primary factors guiding antidepressant therapy during pregnancy and the postpartum period.

Unlike pulmonary hypertension in adults and older children, few genetic risk factors for PPHN have been identified. Children with Down syndrome (trisomy 21) commonly develop pulmonary hypertension in association with structural heart defects but also have a 10-fold increased risk of idiopathic PPHN. In a Dutch cohort, PPHN was documented in 5.2% of Down syndrome infants (Weijerman et al., 2010), and other studies have shown that Down syndrome infants are overrepresented in neonates requiring ECMO support (Southgate et al., 2001). Polymorphisms of genes for bone morphogenetic protein receptor or other transforming growth factor β receptors, other critical growth factors, or vasoactive enzymes (e.g., NO synthase, phosphodiesterase) have not been shown to increase the risk of neonatal PPHN. In one rigorous genotype analysis of 88 neonates with documented PPHN (Byers et al., 2012), there was a significant association with genetic variants for cortisol signaling (*CRHR1* and *CRHBP*), as well as increased levels of 17-hydroxyprogesterone. These data are supported by animal data indicating that prenatal or postnatal steroid therapy normalizes NO synthase function and improves pulmonary vascular function in experimental PPHN (Chandrasekar et al., 2008; Perezet et al., 2012).

Disruptions of the NO-cGMP, prostacyclin-cAMP, and endothelin signaling pathways play an important role in the vascular abnormalities associated with PPHN. The NO-cGMP pathway has been a topic of particularly intense investigation in the last two decades. Decreased expression and activity of endothelial nitric oxide synthase (eNOS) have been documented in lamb models of chronic intrauterine pulmonary hypertension (Shaul et al., 1997; Villamor et al., 1997), and decreased eNOS expression was found in umbilical venous endothelial cell cultures from human infants with meconium staining who developed PPHN (Villaneuva et al., 1998). These important findings were rapidly followed by clinical testing of iNO, leading to its adoption as the primary vasodilator therapy for PPHN. However, numerous other signaling abnormalities limit the effect of endogenous or exogenous NO. In PPHN, expression and activity of soluble guanylate cyclase are decreased, and cGMP phosphodiesterase activity is increased, leading to lower cGMP levels and limitation of NO-induced vasodilation. Oxidant stress associated with vascular dysfunction and/or exposure to hyperoxia can oxidize and reduce soluble guanylate cyclase activity and increase cGMP phosphodiesterase activity, accentuating these vascular abnormalities.

Prostacyclin is important in the normal pulmonary vascular transition, although less is known about abnormal prostacyclin-cAMP signaling in PPHN. Data from animal models suggest reductions in prostacyclin synthesis and downstream adenylate cyclase responses, analogous to the abnormalities reported for NO-cGMP signaling (Shaul et al., 1991; Lakshminrusimha et al., 2009a). In addition, production of thromboxane, a vasoconstrictor arachidonic acid metabolite, plays a role in pulmonary hypertension produced by chronic hypoxia (Fike et al., 2005). Circulating levels of the potent vasoconstrictor endothelin 1 (ET-1) are elevated in lambs and newborns with PPHN (Rosenberg et al., 1993; Christou et al., 1997). Endothelin effects are mediated through two receptors: ET_A receptors on smooth muscle cells that mediate vasoconstriction and ET_B receptors on endothelial cells that mediate vasodilation, and the balance of endothelin receptors is shifted to the vasoconstrictor (ET_A) pathways in PPHN (Ivy et al., 1998b). Endothelin may

affect vascular tone by increasing production of vasoconstrictor reactive oxygen species such as superoxide and hydrogen peroxide (Wedgwood et al., 2001) and by decreasing expression and activity of peroxisome proliferator-activated receptor γ , which maintains the vasodilatory balance in the fetal lung.

Other Causes of Neonatal Pulmonary Hypertension

Congenital Diaphragmatic Hernia

CDH affects approximately 1 in 2500–3000 pregnancies when prenatal diagnosis is factored in and represents approximately 8% of all major congenital anomalies. CDH includes abnormal diaphragm development, herniation of abdominal viscera into the chest, and a variable degree of lung hypoplasia. Herniation occurs most often in the posterolateral segments of the diaphragm, and 80% of the defects occur on the left side. Severe CDH develops early in the course of lung development and involves an arrest in the normal patterns of airway branching in both lungs, resulting in reduced lung volume and impaired alveolarization. Abnormal distal vascular and air space growth is likely because of the loss of stretch-induced stimulation of lung development from impaired fetal breathing movements due to disruption of the diaphragm. The pulmonary vascular findings include vascular remodeling superimposed on hypoplasia or pruning of the pulmonary vascular bed, producing increased vascular tone and altered vasoreactivity after birth (Pierro and Thebaud, 2014).

After birth, PVR often remains at suprasystemic levels, causing acute pulmonary hypertension, extrapulmonary right-to-left shunting across the foramen ovale and ductus arteriosus, and profound hypoxemia. High PVR in the newborn with CDH is related to multiple factors, including the small cross-sectional area of pulmonary arteries, structural vascular remodeling, and vasoconstriction with altered reactivity. The mediators of altered pulmonary vascular reactivity in CDH remain under investigation, with substantial evidence pointing to disruptions in NO–cGMP and ET-1 signaling (Keller et al., 2010). The level of vascular endothelial growth factor, a key stimulator of angiogenesis, is increased in the lungs of infants with CDH who died; this has been interpreted as a compensatory mechanism for reduced eNOS expression and NO production (Pierro and Thebaud, 2014). In some infants, chronic pulmonary hypertension will persist for months or years, including structural and functional abnormalities of pulmonary circulation in the ipsilateral and contralateral lung. Cardiac catheterization of infants with prolonged pulmonary hypertension has revealed numerous vascular abnormalities, including left pulmonary artery hypoplasia or stenosis, pulmonary vein stenosis, and delayed venous return (Kinsella et al., 2005).

In addition to pulmonary vascular disease, it is important to appreciate that structural and functional abnormalities of the left ventricle create a relative left ventricular hypoplasia that impairs filling and creates pulmonary venous hypertension. Often, newborns with severe CDH have severe pulmonary hypertension with right-to-left shunting at the ductus arteriosus but have left-to-right shunting at the atrial septum because of high left atrial pressure from left ventricular dysfunction (Gien and Kinsella, 2016). This circulatory pattern will diminish the clinical response to iNO during the first few days after birth and produce significant pulmonary and systemic hemodynamic instability. Some infants may have exceptionally severe left ventricular dysfunction that leads to dependence on the right ventricle for systemic perfusion; this subset

of patients may benefit from a management approach that maintains patency of the ductus arteriosus, reduces left ventricular afterload, and delays the use of iNO until left ventricular performance improves (McNamara et al., 2013; Abman et al., 2015). In addition to its role in the acute setting, left ventricular dysfunction can contribute to the severity of pulmonary hypertension during the late and chronic courses in infants with CDH.

Alveolar Capillary Dysplasia

Unlike pediatric and adult pulmonary hypertension, few genetic factors have been identified for PPHN. A notable exception is alveolar capillary dysplasia with misalignment of lung vessels, a rare but universally lethal cause of pulmonary hypertension in the newborn (Bishop et al., 2011). Shortly after birth, affected infants typically exhibit cyanosis, minimal parenchymal disease, and respiratory distress refractory to all known therapies, including extracorporeal support, although later presentations (at several weeks or months of age) have been recognized. More than 50% of infants exhibit other anomalies, most commonly affecting the genitourinary, cardiovascular, and gastrointestinal systems. The diagnosis is established by direct examination of lung tissue by lung biopsy or autopsy. Characteristic findings include simplification of lung architecture, widened and poorly cellular septa with a paucity of capillaries, and strikingly muscularized small arterioles. “Misaligned pulmonary veins” have been described within the same adventitial sheath as pulmonary arteries; these were recently identified to be congested bronchial veins that represent intrapulmonary vascular anastomoses creating right-to-left intrapulmonary shunts and profound refractory hypoxemia (Galambos et al., 2014). Approximately 10% of reported alveolar capillary dysplasia cases have a familial association, and mutations or deletions in the transcription factor forkhead box F1 gene (*FOXF1*) or deletions upstream of *FOXF1* are identified in 40% of infants with alveolar capillary dysplasia (Stankiewicz et al., 2009). A murine model of forkhead box F1 deficiency has been studied, which demonstrates the importance of the forkhead box F1 in embryonic development of the pulmonary vasculature (Kalinichenko et al., 2001).

Pulmonary Hypertension in Premature Infants

Fetal physiologic studies in lambs and humans have shown that the pulmonary vascular response to oxygen does not develop until the latter part of gestation (Morin et al., 1988; Rasanen et al., 1998). However, pulmonary vasoconstriction and reactivity can contribute to high PVR in early preterm lambs, as demonstrated by an increase in PVR with NO synthase inhibition and marked responsiveness to iNO (Kinsella et al., 1994). Birth at 23–26 weeks’ gestational age is associated with high rates of PPHN (Aikio et al., 2012), particularly when associated with oligohydramnios, and high rates of clinical use of iNO have been reported for these gestational ages in regional databases (Handley et al., 2016). Furthermore, echocardiographic findings suggestive of pulmonary hypertension, such as ventricular septal wall flattening and right ventricular dilation, were found in approximately 40% of extremely low birth weight babies at 7 days of age and predicted BPD and late pulmonary hypertension (Mourani et al., 2015).

BPD has emerged as an important cause of chronic pulmonary hypertension, with an incidence of 16%–25% in infants with BPD (Mourani and Abman, 2015). Severe or prolonged pulmonary hypertension increases the risk of late morbidity and death to nearly 50% (Khemani et al., 2007). The pathogenesis of pulmonary

hypertension associated with BPD involves complex interactions between prenatal factors, such as growth restriction, preeclampsia, oligohydramnios, or fetal inflammation, and postnatal injury due to ventilator-induced lung injury, hyperoxia, hemodynamic stress, and infection. The result is impaired angiogenesis, abnormal vascular signaling, and vascular pruning, resulting in a reduction in the alveolar–capillary surface area. Identifying pulmonary hypertension in infants with BPD requires a high index of suspicion and systematic longitudinal evaluation. Echocardiography remains the most practical screening tool and should be considered in infants who continue to have cyanotic spells or require oxygen supplementation at 36 weeks' corrected gestational age. In infants with evidence of significant pulmonary hypertension by echocardiogram, cardiac catheterization may provide a more accurate quantification of the severity of disease, as well as allow vasoreactivity testing (Mourani et al., 2008).

Clinical Evaluation of Persistent Pulmonary Hypertension of the Newborn

PPHN typically presents as respiratory distress and cyanosis within hours of birth and may be associated with a variety of lung and/or cardiac disorders (Box 52.1). Clinically, PPHN is most often recognized in the term or near-term neonate but should also be considered in premature neonates who have cyanosis out of proportion to their parenchymal lung disease (Kinsella et al., 2016). While PPHN is often associated with signs of perinatal distress, such as asphyxia, low Apgar scores, or meconium staining, idiopathic PPHN can present without signs of acute perinatal distress.

PPHN is characterized by hypoxemia that is poorly responsive to supplemental oxygen. An important goal for the initial clinical evaluation is to rule out cyanotic cardiac disease and to determine whether a hypoxemic infant has PPHN-type physiology. Because a patent foramen ovale and ductus arteriosus are normally present early in life, elevated PVR in the newborn will produce extrapulmonary shunting of blood through these fetal channels, leading to severe and potentially unresponsive hypoxemia. In the presence of right-to-left shunting across the patent ductus arteriosus, “differential cyanosis” is often present, which is difficult to observe by physical examination but may be detected by a gradient in PaO₂ and/or oxygen saturation between the right radial artery versus descending aorta sites. Considering the left subclavian artery may have either a preductal or a postductal origin from the aorta, the oximeter probe should be applied to a foot for postductal pulse oximetry monitoring. Saturation differences greater than 5%–10% are generally a significant sign of PPHN, but it is important to remember that a similar pattern of postductal desaturation may be observed in ductus-dependent cardiac diseases, including hypoplastic left-sided heart syndrome, coarctation of the aorta, or interrupted aortic arch.

In many infants, intrapulmonary shunt or ventilation–perfusion mismatch resulting from parenchymal lung disease is the predominant abnormality rather than shunting of blood flow across the patent ductus arteriosus and patent foramen ovale. In this setting, hypoxemia is the result of pulmonary arterial blood perfusing the nonaerated lung regions. Although PVR is often elevated in hypoxemic newborns without PPHN, high PVR does not contribute significantly to hypoxemia in these cases. Rapid improvement in response to supplemental oxygen or increased mean airway pressure suggests ventilation–perfusion mismatch due to primary lung disease, although this may not be obvious with severe parenchymal

• BOX 52.1 Disorders Associated With Neonatal Pulmonary Hypertension

Pulmonary

Meconium aspiration syndrome
Respiratory distress syndrome (term and preterm newborns)
Lung hypoplasia—primary
Congenital diaphragmatic hernia
Pneumonia/sepsis
Idiopathic pulmonary arterial hypertension
Transient tachypnea of the newborn
Developmental and genetic lung diseases, including:

- Alveolar capillary dysplasia (e.g., *FOXF1*)
- Genetic lung disease associated with surfactant proteins, ABCA3, TTF-1, and other proteins
- Pulmonary interstitial glycogenosis
- Congenital lobar emphysema (rare association)
- Cystic adenomatoid malformation (rare association)

Cardiovascular

Myocardial dysfunction (asphyxia; infection; stress)

Structural cardiac diseases:

- Mitral stenosis, cor triatriatum
- Endocardial fibroelastosis
- Pompe disease
- Aortic atresia, coarctation of the aorta, interrupted aortic arch
- Transposition of the great vessels
- Ebstein anomaly, tricuspid atresia

Pulmonary atresia

Hepatic arteriovenous malformations

Cerebral arteriovenous malformations

Pulmonary venous abnormalities:

- Total anomalous pulmonary venous return
- Pulmonary vein stenosis (isolated)
- Pulmonary capillary hemangiomatosis
- Pulmonary veno-occlusive disease

Associations With Other Conditions

Neuromuscular disease

Metabolic disease

Polycythemia

Thrombocytopenia

Maternal drug use or smoking

ABCA3, Member A3 of ATP binding cassette family; TTF-1, thyroid transcription factor 1.

lung disease. Furthermore, most infants with PPHN have at least a transient improvement in oxygenation in response to interventions such as high inspired oxygen concentration therapy and/or mechanical ventilation. Therefore these clinical findings can only suggest and not confirm the diagnosis. At present, there is no single biochemical marker that has emerged with sufficient sensitivity and specificity for the diagnosis and management of PPHN.

Radiographic findings are variable, depending on the primary disease associated with PPHN. Classically, the lung on a chest X-ray in idiopathic PPHN is oligemic, normally or slightly hyperinflated, and lacks parenchymal infiltrates. In general, the degree of hypoxemia is disproportionate to the severity of radiographic evidence of lung disease. Laboratory findings may include hypoglycemia, hypocalcemia, polycythemia, and thrombocytopenia.

Echocardiography is the gold standard to confirm the diagnosis and is an important tool for monitoring the response to therapy. The initial echocardiographic evaluation rules out structural heart disease causing hypoxemia or ductal shunting (e.g., coarctation of the aorta or total anomalous pulmonary venous return), determines

the predominant direction of shunting at the patent foramen ovale and patent ductus arteriosus, and assesses ventricular function. The diagnosis of PPHN is made with certainty if bidirectional or predominantly right-to-left shunting across the foramen ovale or ductus arteriosus is observed, although other signs such as flattening or left deviation of the intraventricular velocity, tricuspid regurgitant velocity, and increased right ventricular dilation also suggest the diagnosis. The echocardiogram is also critical for the evaluation of right and left ventricular function. In some infants, predominant right-to-left shunting at the ductus arteriosus associated with left-to-right shunt at the foramen ovale is observed, indicating a significant contribution of left ventricular dysfunction to the underlying pathophysiology. When severe left ventricular dysfunction accompanies pulmonary hypertension, pulmonary vasodilation alone may be ineffective in improving oxygenation and must be accompanied by targeted therapies to increase cardiac performance and decrease left ventricular afterload. Thus careful echocardiographic assessment provides invaluable information about the underlying pathophysiology and will help guide the course of treatment.

General Management

The American Heart Association and the American Thoracic Society recently developed guidelines for management of pediatric pulmonary hypertension, including PPHN (Abman et al., 2015; Box 52.2). The general management principles for PPHN include maintenance of normal temperature (except for those undergoing therapeutic hypothermia), electrolytes (particularly calcium), glucose, hemoglobin, and intravascular volume. Mechanical ventilation is usually required to optimize lung volumes, although few guidelines exist to standardize ventilator management. Some advocate a “gentle ventilation” approach, with avoidance of paralysis and blood gas goals consisting of PaO_2 of 50–70 mmHg and PaCO_2 of 40–60 mmHg. This strategy has never been rigorously tested (Wung et al., 1985) but may well be the optimal strategy for infants still in the early phases of disease. When significant parenchymal lung disease is present, lung recruitment strategies, such as high-frequency ventilation, improve lung expansion and amplify the response to iNO (Kinsella et al., 1997; Kinsella and Abman, 2000). However, care should be taken to avoid settings that may cause lung overdistension, which can lead to inflammatory changes, pulmonary edema, and decreased lung compliance, all of which can exacerbate pulmonary hypertension.

Use of surfactant should be considered only for infants with parenchymal lung disease. Single-center trials have shown that surfactant improves oxygenation, reduces air leak, and reduces the need for ECMO in infants with meconium aspiration (Findlay et al., 1996). A multicenter trial showed benefit in infants with parenchymal lung diseases such as meconium aspiration syndrome and sepsis (Lotze et al., 1998). This trial also demonstrated the greatest benefit for infants with earlier or milder disease (oxygenation index 15–22) but no benefit in the subset of newborns with idiopathic PPHN. A recent systematic review and metaanalysis of surfactant therapy for neonates with meconium aspiration syndrome showed that those who received bolus surfactant needed ECMO less often than controls. However, the limited number of studies and neonates enrolled led the authors to conclude that more studies are urgently needed to evaluate the efficacy and cost-effectiveness of this therapy (Natarajan et al., 2016). Registry studies indicate that surfactant therapy does not benefit the infant with CDH (Van Meurs, 2004).

• BOX 52.2 American Heart Association and American Thoracic Society Management Guidelines for Persistent Pulmonary Hypertension of the Newborn

1. Inhaled nitric oxide therapy is indicated to reduce the need for extracorporeal membrane oxygenation (ECMO) support in term and near-term infants with persistent pulmonary hypertension of the newborn (PPHN) or hypoxemic respiratory failure who have an oxygenation index that exceeds 25 (class I, level A).
2. Lung recruitment strategies can improve the efficacy of inhaled nitric oxide therapy and should be applied in patients with PPHN associated with parenchymal lung disease (class 1, level B).
3. ECMO support is indicated for term and near-term neonates with severe pulmonary hypertension and/or hypoxemia that is refractory to inhaled nitric oxide therapy and optimization of respiratory and cardiac function (class I, level A).
4. Evaluation for disorders of lung development, such as alveolar capillary dysplasia and genetic surfactant protein diseases, is reasonable for infants with severe PPHN whose condition fails to improve after vasodilator, lung recruitment, and/or ECMO therapy (class IIa, level B).
5. Sildenafil use is a reasonable adjunctive therapy for infants with PPHN who are refractory to inhaled nitric oxide therapy, especially with an oxygenation index that exceeds 25 (class IIa, level B).
6. Inhaled prostacyclin analogues may be considered as adjunctive therapy for infants with PPHN who are refractory to inhaled nitric oxide therapy and have an oxygenation index that exceeds 25 (class IIb, level B).
7. Intravenous administration of milrinone is reasonable therapy for infants with PPHN and signs of left ventricular dysfunction (class IIa, level B).
8. Inhaled nitric oxide can be beneficial for preterm infants with severe hypoxemia that is primarily due to PPHN physiology rather than parenchymal lung disease (class IIa, level B).
9. Inhaled nitric oxide therapy and other pulmonary arterial hypertension–targeted drug therapies should be used cautiously in individuals with congenital diaphragmatic hernia, especially in those with confirmed or suspected left ventricular dysfunction (class IIa, level B).

Acidosis is a pulmonary vasoconstrictor, particularly when combined with hypoxia (Rudolph and Yuan, 1966), and pH should be maintained above 7.30. However, alkalosis (pH >7.45) is not recommended. The use of alkalosis was frequent before the approval of iNO therapy, based on studies that found transient increases in PaO_2 after acute hyperventilation (Drummond et al., 1981). However, the pulmonary vascular response to alkalosis is transient, and prolonged alkalosis may paradoxically worsen pulmonary vascular tone, reactivity, and permeability edema (Laffey et al., 2000). Furthermore, alkalosis produces cerebral vasoconstriction, reducing cerebral blood flow and oxygen delivery to the brain, and may be associated with worse neurodevelopmental outcomes (Ferrara et al., 1984). Similarly, there is no evidence to suggest that the use of sodium bicarbonate infusions to induce alkalosis provides any short-term or long-term benefit (Walsh-Sukys et al., 2000).

Systemic hemodynamics should be optimized, with use of volume to provide sufficient preload and cardiostimulant therapy to enhance cardiac output and systemic O_2 transport. Systemic hypotension may worsen right-to-left shunting, impair oxygen delivery, and worsen gas exchange in patients with parenchymal lung disease. In addition, high right ventricular systolic pressure reduces systolic

flow through the right coronary artery, and low systemic blood pressure leads to a decline in right coronary artery diastolic flow, so correction of both hemodynamic abnormalities is key to avoiding right ventricular ischemia (Giesinger and McNamara, 2016). However, the goal is more complex than simply increasing blood pressure, and careful attention should be paid to right and left ventricular function and the choice of medication. Front-line agents typically include dopamine (5–20 µg/kg per minute) and milrinone

(0.2–0.99 µg/kg per minute). Milrinone, which inhibits cAMP phosphodiesterase 3 (PDE3) activity in cardiomyocytes and pulmonary and systemic arterial smooth muscle, is viewed as an “inodilator” that may be especially useful in the context of left ventricular dysfunction and pulmonary venous hypertension (James et al., 2015). Recent anecdotal evidence supports the use of arginine vasopressin for severe PPHN (Table 52.1), based on its ability to raise systemic pressure via V_1 receptors, and to reduce

TABLE 52.1

Pharmacologic Management of Persistent Pulmonary Hypertension of the Newborn

| Drug | Dose | Mechanism of Action | Adverse Reactions/ Safety Monitoring | Indications |
|----------------------|--|---|--|---|
| Inhaled nitric oxide | 5–20 ppm | Activates soluble guanylate cyclase in vascular smooth muscle cells Selective pulmonary vasodilator Low doses (<10 ppm) enhance ventilation–perfusion matching with parenchymal lung disease (“microselective effects”) | Rebound PH with rapid discontinuation of inhaled nitric oxide therapy Methemoglobinemia with higher doses | Hypoxemic respiratory failure with PPHN |
| Sildenafil (Revatio) | Intravenous: loading dose: 0.4 mg/kg in 3 h Maintenance dose 1.6 mg/kg per day | Selective PDE5 inhibitor that increases vascular cGMP levels and pulmonary vascular relaxation | Hypotension (particularly with rapid loading dose) Hypoxemia | PPHN refractory to inhaled nitric oxide therapy and other conventional therapies |
| Milrinone | Intravenous: loading dose: 0.75 µg/kg per minute for 3 h (for infants with hypotension or severe illness, may choose to not use loading dose) Maintenance dose: 0.2–0.33 µg/kg per minute. Increasing by 0.33 µg/kg per minute to a maximum of 0.99 µg/kg per minute | PDE3 inhibitor that increases cAMP levels Improves cardiac performance through reduced systemic afterload, enhanced contractility, and pulmonary vasodilation | Hypotension, thrombocytopenia, arrhythmias | Left ventricular dysfunction, poor cardiac output |
| Prostacyclin | Flolan: Inhaled: 20–100 ng/kg per minute. Start at 2 ng/kg per minute and increase to 20 ng/kg per minute within 3 h. Continuous intravenous infusion: starting dose: 1–2 ng/kg per minute, incremental increases as tolerated, monitor newborn for tachyphylaxis Remodulin: Continuous infusion: 1.25 ng/kg per minute to start, titrate up slowly to 10 ng/kg per minute Can be delivered subcutaneously in the same dosing range | Activates adenylate cyclase in vascular smooth muscle cells Pulmonary vasodilator | Ventilation–perfusion mismatch may complicate use in the setting of lung disease. Nonselective vasodilator, can cause systemic hypotension Risk of rebound PH with sudden withdrawal Flushing, diarrhea | PPHN refractory to iNO therapy and other conventional therapies |
| Bosentan | Enteral: 1–2 mg/kg every 12 h | Dual ET_A and ET_B receptor inhibitor | Hepatotoxicity, edema, anemia, teratogen Monitor monthly LFT results. | PPHN refractory to iNO and other conventional therapies Generally used for chronic PH (CDH, BPD) |
| Vasopressin | 0.0003–0.004 units/kg per minute | Predominantly used for enhancement of systemic hemodynamics in severe PPHN May have pulmonary vasodilator effects via activation of eNOS | Hypotension, arrhythmias Hyponatremia: increases cAMP level in distal tubules, leading to decreased urine volume | |

pulmonary arterial pressure via activation of NO synthase (Mohamed et al., 2014).

Infants who fail to respond to medical treatment, as evidenced by failure to sustain improvement in oxygenation with good hemodynamic function, may require treatment with ECMO (UK Collaborative ECMO Trial Group, 1996). ECMO is the only proven lifesaving rescue modality for severe PPHN, although it is also costly, labor-intensive, and associated with potential adverse effects, such as intracranial hemorrhage and ligation of the right common carotid artery. The oxygenation index (calculated as $[\text{mean airway pressure} \times \text{FiO}_2 \times 100]/\text{PaO}_2$) is used to gauge the severity of disease, with an oxygenation index greater than 40 used as an indication for transfer to an ECMO center. Even with all available therapies, the mortality for PPHN remains between 5% and 10%.

Oxygen

Supplemental oxygen is a mainstay of PPHN therapy to maintain oxygen delivery to the brain and other tissues and for its pulmonary vasodilator properties. Alveolar hypoxia and hypoxemia should be avoided, as both are pulmonary vasoconstrictors and contribute to the pathophysiology of PPHN. On the other hand, the degree of hyperoxic ventilation needed for pulmonary vasodilation remains under investigation. The use of oxygen concentrations greater than 60% has not been shown to provide any additional benefit in pulmonary vasodilation. On the other hand, hyperoxic ventilation increases oxidant stress and lung injury and may paradoxically impair the vasodilator response to iNO. Therefore the oxygen concentration and PaO_2 should be titrated to maximize pulmonary vasodilation. Studies in newborn lambs suggest that the lowest PVR can be maintained with a preductal SpO_2 in the 91%–97% range with preductal PaO_2 between 60 and 80 mmHg (Lakshminrusimha et al., 2007, 2009b). Overall, oxygen should be used like any other drug in the therapeutic context, considering its potential benefits and side effects.

Inhaled Nitric Oxide

The primary goal of PPHN therapy is selective pulmonary vasodilation. Inhaled NO (iNO) is FDA approved as a specific pulmonary vasodilator therapy for PPHN, based on extensive safety and efficacy data from large placebo-controlled trials (Abman et al., 2015). It is well suited for the treatment of PPHN. It is a rapid and potent vasodilator, and because NO is a small gas molecule, it can be delivered as inhalation therapy to air spaces approximating the pulmonary vascular bed. Inhaled NO immediately improves oxygenation and decreases the need for ECMO support in newborns with PPHN and an oxygenation index greater than 25. The appropriate starting dose is 20 ppm; higher doses in nonresponders did not improve immediate responses or outcomes (Neonatal Inhaled Nitric Oxide Study Group, 1997), and treatment with high NO doses (80 ppm) increases the risk of methemoglobinemia (Davidson et al., 1998). Similarly, to term infants, preterm infants with early PPHN, particularly after prolonged rupture of membranes or oligohydramnios, will show marked improvement in oxygenation after treatment with iNO (Kinsella et al., 2016). Recent reports indicate that iNO use ranges from 4% to 8% in extremely preterm infants (Handley et al., 2016).

The optimal window for introduction of iNO therapy remains uncertain. The initial randomized trials studied term and near-term infants with severe PPHN and an oxygenation index of 25–40 (Neonatal Inhaled Nitric Oxide Study Group, 1997; Clark et al.,

2000). A subsequent large trial tested earlier use of iNO in infants with moderate respiratory failure (median oxygenation index of approximately 20) but did not report reductions in ECMO use/death relative to controls (16.7% vs 19.5%; Konduri et al., 2004, 2007). Once an infant has stabilized, weaning can generally be accomplished in 4 to 5 days. Prolonged need for iNO therapy without resolution of disease should lead to a more extensive evaluation to determine whether other underlying anatomic lung or cardiovascular disease is present, such as pulmonary venous stenosis, alveolar capillary dysplasia, and severe lung hypoplasia.

Up to 40% of infants will not respond or sustain a response to iNO. The reasons for an inadequate response are diverse and require the clinician to carefully analyze the relative roles of parenchymal lung disease, pulmonary vascular disease, and cardiac dysfunction for each infant. For instance, if severe air space disease is associated with PPHN, strategies such as high-frequency ventilation that optimize lung expansion are likely to be effective, and the two therapies used together are more effective than either used individually (Kinsella et al., 1997). Considering iNO is usually delivered with high concentrations of oxygen, these therapies could interact and lead to enhanced production of reactive oxygen and reactive nitrogen metabolites, both of which may contribute to vasoconstriction and/or inadequate responses to iNO.

Other Therapeutic Agents

Phosphodiesterase Inhibitors

Increased activity of PDE5 has been consistently reported in experimental models of PPHN (Hanson et al., 1998; Farrow et al., 2010). More recently, in vitro and in vivo studies have shown that even brief periods of hyperoxia independently increase the activity of PDE5, by a mechanism that appears to involve reactive oxygen species (Farrow et al., 2008, 2010, 2012). This finding could partially explain why some infants do not respond favorably to iNO.

Sildenafil is the best studied of the available phosphodiesterase inhibitors and can be administered by the enteral and intravenous routes. A small randomized trial found that enteral administration of sildenafil improved oxygenation and survival in term and late preterm neonates with PPHN (Baquero et al., 2006). In a subsequent dose-finding study, intravenous administration of sildenafil improved oxygenation in neonates with and without concurrent iNO treatment (Steinhorn et al., 2009), suggesting that sildenafil may be a useful adjunct in patients with partial or poorly sustained responses to iNO. Theoretically, sildenafil may be particularly effective in neonates with PPHN following prolonged hyperoxic ventilation, considering PDE5 expression and activity are increased following ventilation with high concentrations of oxygen and exposure to reactive oxygen species. Sildenafil is generally well tolerated, although hypotension can occur, particularly if a loading dose is given too rapidly (Steinhorn et al., 2009). The availability of sildenafil as an enteral preparation also makes it feasible for long-term therapy for infants with chronic pulmonary hypertension associated with CDH (Keller et al., 2006) and BPD (Mourani et al., 2009), although this aspect of treatment needs more study and long-term follow-up. Other phosphodiesterase inhibitors include tadalafil and vardenafil, but their use in PPHN has not yet been reported.

Prostanoids

Prostacyclin (epoprostenol) was approved by the FDA in 1995 for the treatment of adult pulmonary arterial hypertension. While

intravenously administered prostacyclin remains a mainstay of therapy for pulmonary hypertension in adults, rapid dosage escalation is often necessary for acute disease and can produce systemic hypotension. Its utility in the neonatal intensive care unit setting is also limited by the need for a dedicated central venous catheter, the potential to worsen ventilation–perfusion matching, and other systemic side effects including pain.

Aerosolized prostacyclin has been widely adopted in adult critical care units for the treatment of pulmonary hypertension (Walmrath et al., 1996). While fewer reports describe its use in infants, case series indicate that continuous inhaled prostacyclin therapy (50–100 ng/kg per minute) is well tolerated and improves oxygenation in infants with severe PPHN and inadequate response to iNO (Kelly et al., 2002; Porta and Steinhorn, 2012). The risks include airway irritation from the alkaline solution needed to maintain drug stability, rebound pulmonary hypertension if use of the drug is abruptly discontinued, and inconsistent drug delivery due to drug loss into the circuit. New, stabler preparations are emerging that are specifically designed for intermittent nebulization, such as iloprost or treprostinil. Treprostinil is particularly promising because it is also suitable for systemic administration, including by the subcutaneous route (Ferdman et al., 2014).

Inhibition of PDE3, which metabolizes cAMP, might also enhance cAMP signaling in PPHN (Chen et al., 2009). Milrinone, a PDE3 inhibitor, has been shown to decrease pulmonary arterial pressure and resistance and to act additively with iNO in animal studies (Thelitz et al., 2004). A report indicates that the addition of intravenous milrinone therapy for neonates with severe PPHN and poor iNO responsiveness was associated with improvements in oxygenation without hemodynamic status being compromised (McNamara et al., 2006).

Endothelin Receptor Antagonists

ET-1 is a potent vasoconstrictor synthesized by vascular endothelial cells that acts through two receptors, ET_A and ET_B. The ET_A receptor plays a critical role in vasoconstriction, and selective blockade of the ET_A receptor causes fetal pulmonary vasodilation (Ivy et al., 1994). *ET-1* gene expression and ET-1 levels are increased in the lungs and pulmonary arterial endothelial cells in the fetal

lamb model of PPHN (Ivy et al., 1998a; Gien et al., 2013). Long-term intrauterine ET_A receptor blockade following ductal ligation decreases pulmonary arterial pressure and distal muscularization of small pulmonary arteries in utero, decreases right ventricular hypertrophy, and increases the fall in PVR at delivery in newborn lambs with PPHN (Ivy et al., 1997). Thus it is likely that ET-1, acting through the ET_A receptor, contributes to the pathogenesis and pathophysiology of PPHN. Use of bosentan, a nonspecific ET-1 receptor blocker, is an established therapy for pulmonary hypertension in adults. Two recent trials show that bosentan is well tolerated in neonates with PPHN. One single-center trial reported that bosentan led to substantial improvements in oxygenation in an iNO-naïve population of PPHN infants (Mohamed and Ismail, 2012), but the FUTURE-4 multicenter trial found that bosentan as an adjunctive therapy with iNO therapy did not improve PPHN outcomes, reduce the time in receipt of iNO therapy, or reduce the time to extubation, possibly in part due to inconsistent intestinal absorption (Steinhorn et al., 2016).

Outcomes

Early reports began to establish the high risk of death and abnormal neurodevelopmental outcomes for survivors of PPHN (Bifano and Pfannenstiel, 1988). At least one report showed that oxygenation (measured by the alveolar–arterial oxygen difference) correlated well with survival but not with long-term outcome (Hageman et al., 1988). Some reports further indicated that low Apgar scores and prolonged hypoxemia were predictive of adverse neurodevelopmental outcomes (Bifano and Pfannenstiel, 1988; Marron et al., 1992).

The long-term outcome data for the largest iNO trials are summarized in Table 52.2, which also provides the most comprehensive outcome data for PPHN infants treated with and without iNO. Overall, these results highlight that neurodevelopmental impairment is high in this population (14%–30%) and is not reduced by iNO therapy (Neonatal Inhaled Nitric Oxide Study Group, 2000; Lipkin et al., 2002; Clark et al., 2003; Konduri et al., 2007). In each of these trials, a trend toward higher motor impairment was observed in the iNO group, and in the early iNO trial reported by Konduri et al. (2007), the difference in the Bayley

Neurodevelopmental Outcomes for the Major Inhaled Nitric Oxide Clinical Trials

| Study | Number of Participants | Initial OI | Age at Follow-Up (Months) | NDI (%) | | BAYLEY MENTAL DEVELOPMENTAL INDEX | | BAYLEY PSYCHOMOTOR DEVELOPMENTAL INDEX | | CEREBRAL PALSY (%) | |
|--|------------------------|------------|---------------------------|---------|-----|-----------------------------------|----------------|--|----------------|--------------------|------|
| | | | | Control | iNO | Control | iNO | Control | iNO | Control | iNO |
| Neonatal Inhaled Nitric Oxide Study Group (2000) | 235 | 44 | 18–24 | 30 | 35 | 87 | 85 | 93.6 | 85.7 | 10.3 | 11.8 |
| Clark et al. (2003) | 248 | 39 | 12 | 14 | 19 | 95 | 95 | 85 | 92 | 1.4 | 4 |
| Davidson (2002) ^a | 155 | 24.7 | 12 | 20 | 18 | — ^b | — ^b | — ^c | — ^b | 6 | 8 |
| Konduri et al. (2007) | 299 | 19.2 | 18–24 | 25 | 28 | 86.1 | 83.3 | 98 | 89 | 6.3 | 8.2 |

^aThe reference reporting the outcomes for the Davidson trial is entered as Lipkin 2002.

^bSeventy-one percent of the control group and 69% of the inhaled nitric oxide (iNO) group were reported as normal (mental developmental index ≥85).

^cEighty-two percent of the control group and 76% of the iNO group were reported as normal (psychomotor developmental index ≥85).

NDI, Neurodevelopmental impairment; OI, oxygenation index.

psychomotor developmental index was statistically significant. The Neonatal Inhaled Nitric Oxide Study Group (2000) reported that the rate of disability was not affected by the need for ECMO, leading the authors to speculate that the timing of brain injury was most likely before ECMO.

Neurodevelopmental impairment is high even for those infants with moderate PPHN (oxygenation index of 15–25). The overall rates of neurodevelopmental impairment were similar to those of other trials that enrolled patients with more advanced disease, and early iNO use did not translate into improved outcomes (Konduri et al., 2007). The proportion of infants with medical problems, such as the need for home medications, oxygen, and gastrostomy feedings, also tended to be higher in the early iNO group, although these differences were not statistically significant.

ECMO is the only PPHN therapy that has been proven to be lifesaving, but it remains a technically complex and invasive therapy with many potential complications. More than 27,000 newborns have been treated with ECMO for respiratory failure, with a cumulative overall survival to discharge of 75% (Paden et al., 2014). Mild to major neurodevelopmental impairment is described in 15%–25% of neonatal ECMO survivors (van Heijst et al., 2014).

Summary

Persistent pulmonary hypertension complicates the course of up to 10% of neonates with respiratory failure. It is associated with a diverse set of cardiopulmonary conditions, and its pathophysiologic mechanisms are characterized by vascular dysfunction, injury, and remodeling that occur before and after birth. In the last 20 years, experimental work on the basic mechanisms of vascular regulation of the developing pulmonary circulation has improved the range of therapeutic approaches for neonates with PPHN. In particular, iNO has proven to be a selective and effective pulmonary vasodilator

However, determining the role of ECMO versus other disease factors in the neurodevelopmental outcomes for ECMO survivors is difficult. From the pre-iNO era, the UK Collaborative Randomized Trial of ECMO provides the most direct comparison of outcomes after ECMO versus conventional treatment and included neurodevelopmental assessments at ages 1, 4, and 7 years. At age 1 year, a significant survival benefit (68% vs 41%) was observed in the ECMO-treated group versus the conventionally treated group (UK Collaborative ECMO Trial Group, 1998), and survivors demonstrated similar rates of impairment or disability. At the 4-year follow-up, there continued to be a higher proportion of survivors without disability in the ECMO-treated group versus the conventionally treated group (50% vs 37%) (Bennett et al., 2001), although the rates of disability were similar at age 7 years (55% vs 50%) (McNally et al., 2006). The high rate of neurodevelopmental impairment in both groups suggests that the underlying disease process, rather than the treatment, is the major influence on neurodevelopmental outcome. Several more recent studies also indicate that ECMO survivors may be at risk of academic problems (Ijsselstijn and van Heijst, 2014), so these children will benefit from detailed assessment as they reach school age.

for infants with PPHN, although successful clinical management requires meticulous care for all aspects of the associated lung and cardiac disease. Current research is focused on developing a better understanding of cellular responses in the remodeled vasculature and will likely elucidate additional signaling pathways and lead to new therapeutic strategies. More work is needed to further reduce mortality and improve neurodevelopmental outcomes of sick newborns with pulmonary hypertension, especially in patients with lung hypoplasia and advanced structural vascular disease.

Fetal and Neonatal Echocardiography

MARGARET M. VERNON AND MARK B. LEWIN

KEY POINTS

- Echocardiography is used to assess cardiac anatomy and physiology.
- Appropriate interpretation requires an understanding of its limitations.

*E*chocardiography is the application of ultrasound to the evaluation of the cardiovascular system. Over the past several decades echocardiography has established itself as the gold standard for the diagnosis of congenital heart disease (CHD) and acquired heart disease. Instrumentation has become more sophisticated, and utilization has moved from an anatomic evaluation to include an assessment of myocardial function; an understanding of the basic principles and limitations of ultrasound is increasingly valuable to clinicians. This chapter reviews the basic principles of echocardiography and their applications in the prenatal and newborn settings.

Application of Ultrasound to Cardiac Imaging

Physics of Ultrasound

Ultrasound is the use of ultra-high-frequency sound waves (those too high in frequency to be heard by the human ear) to create an image. Echocardiography is the application of ultrasound to create an image of the heart. In both, energy is generated by the stimulation of piezoelectric crystals housed in a small handheld device called a transducer. When the transducer is placed on the chest or abdomen, ultrasound waves are transmitted into the tissue. The majority of these waves are absorbed; however, a small subset are reflected (echoed) back to the transducer. These reflected waves are processed, and the resultant image is displayed on the screen. Soft tissue (such as the liver) and fluid (such as blood and amniotic fluid) are excellent media for ultrasound transmission and provide optimal windows for detailed cardiac imaging (Weyman, 1994). Ultrasound scatter, which negatively impacts image clarity, is greatest at the interfaces between biologic tissues of widely disparate densities. Hence, bone and air, when adjacent to soft tissues such as the heart, create poor acoustic windows for ultrasound transmission.

Ultrasound generally refers to sound waves of frequencies greater than 20,000 Hz (cycles per second), with the range of frequencies used for diagnostic assessment of biologic tissue between 2 and 12 megahertz (MHz) (megahertz = 1,000,000 Hz). Low-frequency waves penetrate tissue better than high-frequency ultrasound waves; however, higher-frequency waves provide for greater spatial resolution of fine structures. This principle is dictated by a fundamental law of physics that defines the relationship between ultrasound frequency and wavelength:

$$\text{velocity} = \text{frequency} \times \text{wavelength}$$

An ultrasound wavelength distance is the physical limit beyond which two structures cannot be distinguished. Hence, the shorter the wavelength (i.e., the higher the frequency), the greater the ability to distinguish the two points from each other.

Let us look at the following example: two structures are 0.5 mm apart. The velocity of sound in biologic tissue is a constant, at approximately 1540 m/s. Applying a frequency of 2 MHz of ultrasound energy will result in a wavelength of 0.77 mm, whereas applying a frequency of 8 MHz of ultrasound energy will result in a wavelength of 0.19 mm. Hence, to the operator using the 2 MHz transducer, the two structures will not be distinguishable from one another and will appear as one (in that the distance between them is less than the ultrasound wavelength), whereas the operator using the 8 MHz transducer will be able to differentiate between the structures with ease. Accordingly, higher frequencies, at a minimum 5 MHz and more typically 8–12 MHz, are used in the neonatal setting because penetration is less important, and the objective is to maximize fine structure resolution.

Basic Imaging Components

M-Mode

The earliest form of echocardiographic imaging, M-mode echocardiography, displays the visualized cardiac structures along a single plane of insonation. The displayed image shows the structures as they change over the cardiac cycle. Today, M-mode echocardiography is primarily used for measurement of ventricular wall thickness, cavity dimensions, and in the calculation of the ventricular *shortening fraction*—an estimate of ventricular function. By angling the plane of insonation through the short axis of the left ventricle at the level of the tips of the papillary muscles, one can obtain an M-mode display of the change in ventricular cavity dimension over time (Fig. 53.1). The ratio of the difference between left

• **Fig. 53.1** M-Mode Tracing of the Left-Ventricular Dimensions Over Time Obtained in the Short-Axis View. The electrocardiographic tracing helps identify the timing of the cardiac cycle as systolic or diastolic. Measurement A demonstrates the left ventricle end-diastolic dimension and measurement B, the left ventricle end-systolic dimension. The shortening fraction is calculated at 35%.

ventricle end-diastolic dimension (LVEDD) and left ventricle end-systolic dimension (LVESD) to the left ventricle end-diastolic dimension is the shortening fraction ($(LVEDD - LVESD)/LVEDD \times 100 = \%SF$). The normal range is 28% to 38%, which correlates with a ventricular volumetric ejection fraction of 55%–65%.

When interpreting a shortening fraction, it is important to note the dimension of the left ventricle. For example, an infant with a ventricular volume load caused by a large patent ductus arteriosus (PDA) may have a normal shortening fraction; however, hemodynamic significance is suggested by the presence of a dilated left ventricle when normalized for body surface area.

The shortening fraction (%SF) also can be helpful in investigating the cause of hypotension in neonates. In the setting of hypotension caused by myocardial dysfunction, the infant will have a diminished %SF frequently accompanied by a dilated left ventricle. Alternatively, when hypotension is secondary to systemic vasodilatation, such as in sepsis, the neonate may have a normal or hyperdynamic %SF, often exceeding 40%. Finally, volume-depleted infants will exhibit a normal %SF with a small left-ventricular cavity size.

Although the %SF is easily calculated and commonly used, it has a number of limitations. It provides for only a single-plane assessment of ventricular contraction and is invalid in conditions in which there is abnormal interventricular septal wall position or motion, including right-ventricular hypertension, right-ventricular enlargement, or a right-bundle branch block (Fig. 53.2).

Two-Dimensional Imaging

The development of phased-array transducers has allowed for sector rather than linear scanning and the display of two-dimensional (2D) images. Today, high-resolution 2D echocardiography is the most commonly applied modality of echocardiography. Detailed, reliable, and reproducible images of cardiac structures can be obtained, and, when images from multiple planes are mentally combined, precise cardiac diagnoses can be made.

Imaging typically follows a standard protocol. Cardiac and abdominal situs are assessed, a complete evaluation of the anatomic structure of the heart and proximal vasculature from multiple

• **Fig. 53.2** M-Mode Tracing of the Left-Ventricular Dimensions Over Time Obtained in the Short-Axis View. The electrocardiographic tracing helps identify the timing of the cardiac cycle as systolic or diastolic. The interventricular septum moves paradoxically (arrow) because of elevated right-ventricular pressure. Therefore a shortening fraction cannot be calculated accurately.

planes is made, and a determination is made as to the functional (systolic and diastolic) properties of the myocardium.

For an accurate determination to be made as to the dimensions of chambers, valves, and vessels, comparison with a normative dataset is required. The most common methodology involves normalizing measurements to body surface area. A number of datasets have been published and are available for comparison. In order to achieve consistency, each pediatric echocardiography laboratory must decide which of these datasets they will use. Various normative (Z-score) calculators are also available online (<http://www.parameterz.com> and <http://zscore.chboston.org/>) with references and descriptors included for ease of use. The identification of a pathologically large or small structure is especially troublesome when the patient is extremely premature. Comparative data for such infants are scant and are often based on data collected from a very small number of “normal” patients. Determination of dimensions (e.g., left ventricle, aortic valve, or pulmonary artery) in such premature patients is therefore subject to a fair bit of interpretation; in these cases, consultation with the pediatric cardiologist is imperative in order to make appropriate management decisions.

2D imaging also allows for an alternate means of measuring the end-diastolic and end-systolic dimensions, thus providing another means of estimating ventricular systolic contractility.

Doppler

Application of the Doppler principle allows for determination of flow direction and velocity of moving objects. As blood and myocardial tissue both are in motion throughout the cardiac cycle, either can be assessed by Doppler echocardiography. Doppler imaging can be performed in a number of ways. In pulsed-wave Doppler echocardiography, single ultrasound crystals alternately fire pulses of energy and then “listen” for reflected signal return. This mode allows for determination of spatial signal position but is limited in its ability to accurately measure blood traveling at higher velocities. In continuous-wave Doppler echocardiography, half of the transducer crystals continuously transmit, while the

other half continuously receive, and all received signals are displayed as a composite. This mode allows for unambiguous assessment of increased velocities but limits the ability to pinpoint the precise location at which the velocity is obtained. In combination, pulsed-wave and continuous-wave Doppler modes provide a complete picture of blood flow direction and velocity.

Color Doppler echocardiography uses pulsed-wave principles to create a 2D sector display of all velocities within a given region of interest. A sector within a 2D image is identified, and pixels of color are displayed overlying the area of interrogation. Each color pixel reflects the direction of motion; the shade of color reflects the velocity. By convention, “warm” colors such as red and orange designate direction of flow toward the transducer, and “cold” colors such as blue and white designate flow away from the transducer (Fig. 53.3). When flow velocities exceed the characteristics of the transducer, the smooth, laminar color pattern changes to a speckled color pattern, suggesting a region of more turbulent flow. Whether this represents a pathologic velocity change requires pulsed Doppler interrogation.

Doppler techniques are also applied to motion of the myocardium (i.e., tissue Doppler), yielding information helpful in ascertaining parameters of myocardial function. Although tissue signals move at much lower velocities than blood signals, determination of Doppler-derived tissue velocities can aid in understanding complex states of systolic and diastolic dysfunction. Distinct patterns of normal and abnormal motion of various myocardial segments have been described (Mertens and Friedberg, 2009).

Extremely premature infants are at risk for bronchopulmonary dysplasia (BPD), also referred to as chronic lung disease of pre-

maturity (see Chapter 48). Primarily in those born at less than 26 weeks' gestation, pulmonary vascular and alveolar growth are disrupted, which can result in abnormal gas exchange and vaso-reactivity. The resultant pulmonary vascular remodeling can be accompanied by a persistent elevation of pulmonary vascular resistance (PVR) and consequent pulmonary hypertension, which in turn can lead to right-ventricular dysfunction and failure. Transthoracic echocardiography, and the comparison of serial studies, is a key clinical tool for monitoring pulmonary hypertension and optimizing treatment plans for those with, or at risk for, chronic lung disease. Right-ventricular pressure (and pulmonary-arterial pressure) can be estimated using the tricuspid regurgitation jet velocity as well as qualitative evidence of pulmonary hypertension (flattening of the interventricular septum and right-ventricular hypertrophy). Recently, novel echocardiographic parameters have been introduced, including the myocardial performance index (Tei index), a marker of ventricular dysfunction calculated by the sum of the isovolumetric contraction and relaxation times divided by the ejection time. This index is elevated in primary pulmonary hypertension and may be elevated in those with BPD. Tissue Doppler measurements have been found to correlate with BPD severity, including the ratio of the early Doppler inflow velocity to the early myocardial tissue Doppler velocity (E/E'). Furthermore, cardiovascular abnormalities are found in many of those with BPD, including large aortopulmonary collaterals, pulmonary vein stenosis, and persistent ductal patency. Right-ventricular function is an important determinant of prognosis in pulmonary hypertension. Noninvasive assessment of the right-ventricular function is often limited by complex geometry and poor endocardial definition. The degree of tricuspid annular displacement (tricuspid annular plane systolic excursion [TAPSE]) is a useful echo-derived measure of right-ventricular function with prognostic significance in pulmonary hypertension, which has recently been validated in the neonatal and pediatric population. TAPSE has been found to be a feasible and reproducible marker of right-ventricular systolic function in infants with pulmonary hypertension and correlates with the severity of pulmonary hypertension (Zakaria et al., 2015).

Data derived from Doppler echocardiography are used to provide physiologic information. Using the principles of flow hydraulics across a tubular system with discrete narrowing, velocity data can be translated into pressure data via modification of the Bernoulli equation (Fig. 53.4).

Normal velocities in the heart are rarely greater than 2 m/s and typically less than 1 m/s. These low velocities proximal to an area of narrowing (V_1) can be ignored and the Bernoulli equation simplified to:

$$\text{pressure change} = 4 \times V_2$$

$$\text{Bernoulli Equation} \\ P_1 - P_2 = 4 \times (V_2 - V_1)^2$$

• **Fig. 53.4** The Bernoulli Equation of Flow Dynamics. The Bernoulli equation of flow dynamics describes the relationship between pressure differences and velocity differences across an area of narrowing in a closed fluid system. P_1 , Proximal pressure; P_2 , distal pressure; V_1 , proximal velocity; V_2 , distal velocity.

• **Fig. 53.3** Side-by-Side Two-Dimensional and Color Doppler Echocardiographic Images of a Ductus Arteriosus. Flow in the patent ductus arteriosus (PDA) is red, indicating flow toward the transducer (in this case left-to-right) and is directed toward the main pulmonary artery (MPA) from the aorta. The PDA color signal is speckled, indicating a more turbulent region of flow. High velocity in the PDA is the normal state, indicating appropriately elevated pressures in the aorta as compared to the lower pressures in the pulmonary artery. The flow in the left pulmonary artery (LPA) is blue, indicating flow away from the transducer. The LPA color flow signal is laminar (smooth), indicating a lower velocity of flow. Turbulent flow at this portion of the LPA in a neonate is most commonly associated with physiologic branch pulmonary artery stenosis, a transient phenomenon associated with neonatal transitional physiology.

This principle can be applied in a variety of clinical settings. For example, in the presence of tricuspid regurgitation (TR), the peak right ventricle pressure (which will equal the pulmonary artery pressure in the absence of pulmonary outflow obstruction) can be estimated by measuring the peak velocity of the regurgitant jet. A TR peak velocity of 2 m/s suggests a pressure difference between the right atrium and the right ventricle of 16 mmHg ($4 \times [2]^2$). We express this as a right-ventricular pressure of 16 mmHg + right-atrial (or central venous) pressure. In infants and children, right-atrial pressure is estimated to be between 3 and 10 mmHg, with 5 mmHg typically chosen as an estimated guess. Hence, in the preceding example, the patient would have a right ventricle pressure of 21 mmHg, which is within normal limits. Alternatively, an infant with severe chronic lung disease may have a TR peak jet of 4.1 m/s (Fig. 53.5). This would translate to a pressure estimate of 64 mmHg ($4 \times [4.1]^2$); 68 mmHg added to the estimated right-atrial pressure of 5 mmHg gives a right ventricle pressure of 73 mmHg, which suggests pulmonary hypertension. The Bernoulli equation is also commonly used to assess pressure gradients across stenotic valves or vessels: for example, aortic valve stenosis or coarctation of the aorta. Using the maximum velocity, we derive the “peak instantaneous” gradient across the site of obstruction. When interpreting a Doppler-derived velocity, it is essential to recognize that the most precise estimates are obtained when the direction of blood flow is parallel to the ultrasound beam. Small changes in the angle of interrogation can introduce large errors in the calculated velocity; therefore the sonographer angles the ultrasound beam until the highest-pitched audio signal is detected, and assessment is attempted from several different echocardiographic windows in order to obtain the highest velocity. Superimposing

color Doppler imaging with pulsed-wave or continuous-wave Doppler makes it possible to visually align the Doppler beam with the flow jet.

Neonatal Echocardiography: Goals of Imaging

As previously mentioned, echocardiography is the most common imaging modality used in the assessment of the neonatal heart. Echocardiography is widely available and noninvasive. Furthermore, the information obtained is real-time, reproducible, and acquired at the bedside. These properties allow for serial assessment and comparison of data points. Echocardiography is established as the gold standard for the diagnosis of CHD, and obtained images frequently support the clinical assessment in the management of a variety of neonatal conditions. The indications for the performance of an echocardiogram in the nursery or newborn intensive care unit include the assessment of the neonate with a presumed syndromic or genetic condition at high risk for cardiac disease (e.g., trisomy 21), the infant with a noncardiac lesion where there is an increased risk of associated CHD (e.g., omphalocele), and the neonate with a condition that may adversely affect hemodynamics (e.g., arteriovenous malformations). These are summarized in Table 53.1.

Serial echocardiographic evaluations are often necessary in order to care for the neonate. This is particularly the case when changes are occurring in the patient’s clinical condition. Left-atrial and left-ventricular chamber dimensions can be followed as PVR drops in order to determine the left-to-right shunt impact in the face of

• **Fig. 53.5** Example of a Doppler Signal. Time is on the x-axis, and velocity is in meters/second on the y-axis. The Doppler signal is obtained by positioning a marker just proximal to the tricuspid valve annulus in order to sample the tricuspid regurgitant (TR) jet flow. In this example the TR peak velocity measures 4.1 m/sec. Using the modified Bernoulli equation, the predicted right-ventricular pressure is $4 \times (4.1)^2 = 68$ mmHg + right-atrial pressure. This predicts elevated right-ventricular pressure (normal is typically in the range of 20 mmHg). In the absence of obstruction to flow through the pulmonary artery, the right-ventricular pressure is equivalent to pulmonary artery pressure. We can therefore quantify pulmonary artery pressure based on the velocity of the TR jet.

TABLE 53.1 Indications for Echocardiographic Evaluation in the Neonate

a PDA or ventricular septal defect (VSD); the notation of left-atrial or left-ventricular dilation in these scenarios suggests the presence of pulmonary overcirculation. The interventricular thickness can be serially measured as can the Doppler pattern and peak velocity across the left-ventricular outflow tract obstruction in the infant of a diabetic mother to assess for baseline hemodynamic impact and improvement over time. The neonatal cardiopulmonary system is a highly fluid system, subject to perturbation from numerous outside influences and thus requires close monitoring in the labile child. Echocardiography is but one tool in the armamentarium of the neonatologist and cardiologist to assist with this monitoring.

Fetal-to-Neonatal Transitional Physiology: Echocardiographic Assessment

During fetal life, the placenta serves as the organ of gas exchange. This fundamental difference between the fetal and neonatal circulations is behind the complex physiologic transition that occurs following birth and clamping of the umbilical cord. With the initiation of respiration and expansion of the lungs, oxygen is brought to the alveoli. This results in a dramatic fall in PVR, with a resultant increase in pulmonary blood flow. Simultaneously, the umbilical cord is clamped, resulting in a sudden increase in systemic vascular resistance (SVR). The combination of this sudden increase in SVR and decrease in PVR leads to a reversal of flow through the ductus arteriosus. In utero, blood flow through the ductus arteriosus was from right-to-left (pulmonary artery to descending aorta) while after birth, the flow direction reverses and now becomes left-to-right (from descending aorta to pulmonary artery). Finally, because of the marked increase in pulmonary blood flow, venous return to the left atrium increases and left-atrial pressure exceeds right-atrial pressure, leading to flap closure of the foramen ovale.

When clinical findings such as tachypnea, tachycardia, or persistent cyanosis suggest an abnormality in transitional physiology, echocardiography is a very useful, noninvasive diagnostic tool. While anything that increases PVR or delays its fall, such as acidosis, hypoxemia, polycythemia, lung disease, or immaturity, may impair the normal neonatal transition, it is the uniqueness of the fetal circulation that allows many complex lesions to be tolerated silently in utero only to unmask themselves during the transitional period.

Suspected Congenital Heart Disease

Alterations from the normal fetal to neonatal transition are most frequently associated with persistent patency of the ductus arteriosus and/or persistently elevated PVR, and the confirmation of the absence of structural heart disease can be extremely helpful to the team caring for an ill neonate, particularly one with a recognized extra-cardiac anomaly. That said, in those in whom CHD is confirmed, high-quality 2D images combined with color and pulsed-wave and continuous-wave Doppler are frequently sufficient for development of a comprehensive management strategy, including the need for prostaglandin therapy and catheter-based or surgical-based interventions (Tworetzky et al., 1999).

Assessment of the Ductus Arteriosus

Before the routine use of echocardiography, a hemodynamically significant PDA was diagnosed clinically by the presence of a murmur, hyperdynamic precordium, bounding and palmar pulses,

increased ventilatory support, and radiographic evidence of cardiomegaly with increased pulmonary vascular markings. In the present era, a complete transthoracic echocardiogram is recommended to not only confirm the presence of a PDA but also to ensure the absence of structural heart defects. Most commonly, treatment is not considered unless there is clinical as well as echocardiographic evidence of hemodynamic significance (Condo et al., 2012). The echocardiographic assessment of a PDA includes an assessment of its size and direction of flow across it. Size is frequently assessed as a ratio of the diameter of the duct to the left pulmonary artery, with a value greater than 1 suggesting a large ductus (Ramos et al., 2010). A large ductus is also suggested by a percentage of retrograde to antegrade flow in the descending aorta of greater than 50% and the presence of left-ventricular enlargement (Sehgal and McNamara, 2009). Additionally, pulsed-wave and continuous-wave Doppler can be used to establish flow velocity and predict the pressure difference between the aorta and pulmonary artery. Finally, the determination of aortic arch sidedness and branching pattern is made should surgical ligation be required (Murdison et al., 1990). The most common finding is that of a left-aortic arch with a left-sided ductus; however, a right-aortic arch with a right-sided ductus can occur and alters the surgical approach to ductal ligation.

Evaluation of Persistent Pulmonary Hypertension

Persistent pulmonary hypertension of the newborn (PPHN), previously referred to as persistent fetal circulation, results when there is a failure of the normal neonatal transition with persistent severe vasoconstriction of the pulmonary vasculature resulting in the maintenance of elevated pulmonary arterial pressure and right-ventricular pressure. Blood continues to bypass the lungs, shunting across the foramen ovale and through the ductus arteriosus and resulting in systemic desaturation. Risk factors for PPHN include meconium aspiration, neonatal asphyxia, infection, and the presence of a congenital anomaly associated with underdevelopment of the lungs such as a diaphragmatic hernia.

In infants with PPHN, transthoracic echocardiography confirms the absence of structural heart disease (specifically, total anomalous pulmonary venous return with obstruction), demonstrates atrial-level and ductal-level shunting, and provides an estimate of pulmonary arterial pressure by measuring the velocity of the tricuspid regurgitation jet, if present. The Doppler pattern in the ductus arteriosus establishes flow direction as well as velocity. From flow velocity a pressure gradient (or lack thereof) between the aorta and pulmonary artery can be estimated by applying the Bernoulli equation (Musewe et al., 1990). The appearance of the Doppler pattern sampled in the branch pulmonary arteries may also provide information about the PVR and response to therapy.

In addition, echocardiography may be used to assess ventricular function in an infant with PPHN (Fig. 53.6). Neonates with PPHN typically have right-ventricular dysfunction (Valdes-Cruz et al., 1981). Although the etiology of cardiac dysfunction in PPHN is unclear, prenatal constriction of the ductus arteriosus has been suggested as one possible mechanism (Morin, 1989).

Extracorporeal membrane oxygenation (ECMO) is frequently used in infants with severe PPHN whose hypoxemia does not respond to mechanical ventilatory support and pulmonary vasodilators such as supplemental oxygen and nitric oxide. Echocardiography can be used to document improvement and identify the etiology of poor circuit flow.

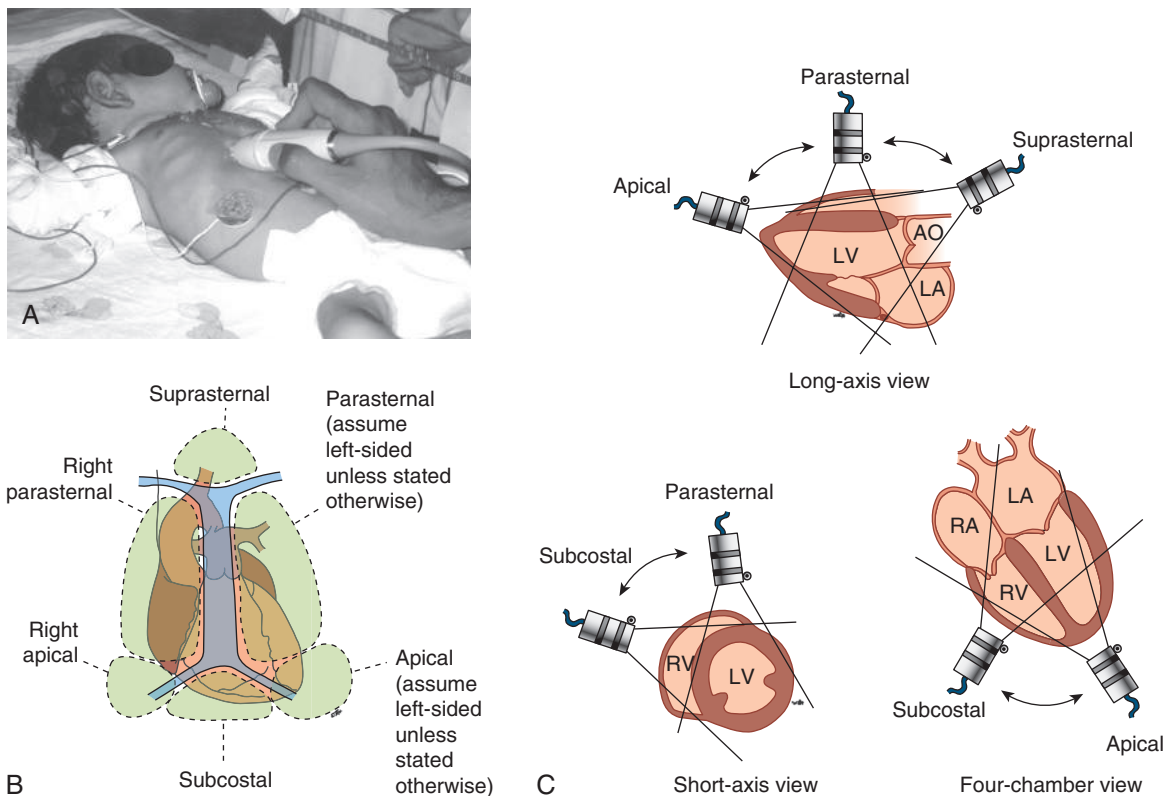

• **Fig. 53.6** Short Axis Imaging of the Ventricles. Normally the left-ventricular pressure exceeds the right, resulting in bowing of the ventricular septum into the right-ventricular cavity. In persistent pulmonary hypertension of the newborn, the right-ventricular pressure (RVp) may be equivalent or even exceed the left-ventricular pressure (LVP), altering the ventricular septal position, as seen in this image where the septum bows abnormally into the left ventricle. This septal position suggests the RVp exceeds the LVP.

Neonatal Imaging Techniques

A systematic and standardized approach is key to performing a comprehensive neonatal echocardiogram. Follow-up studies may be curtailed and limited in scope; however, an initial evaluation should include a detailed assessment of intracardiac and great vessel anatomy using 2D, Doppler, color Doppler, and M-mode imaging. Both still frame and cine clips are obtained. Short cine clips capture both structural motion through the cardiac cycle as well as tomographic cuts of the heart as the transducer is fanned through it. These acquired 2D imaging “sweeps” allow for the “mental reconstruction” of the three-dimensional heart and any complex perturbations from normal. Standard imaging locations are used to create a complete picture of the heart and great vessels (Fig. 53.7). These include images obtained mid-chest (parasternal imaging plane), four-chamber views (apical imaging), and abdominal views through the liver and diaphragm (subcostal imaging) and between the clavicles (suprasternal notch views). Subcostal imaging is unique to neonates and pediatric patients. The liver acts to enhance acoustic transmission, and the proximity of the transducer to the heart optimizes image resolution.

Although echocardiography is a noninvasive diagnostic test, monitoring should be performed during the performance of an echocardiogram, particularly in small, premature infants, as a

• **Fig. 53.7** (A) Demonstration of the position of the ultrasound transducer using the subcostal approach in a neonate. (B) By moving the transducer to multiple windows surrounding the heart, echocardiographic two-dimensional tomographic imaging provides for a three-dimensional look at the heart via “mental reconstruction” once each of the corresponding windows has been examined. (C) Long-axis, short-axis, and four-chamber views of the heart contribute to visualization of the overall detail of complex cardiac anatomy. AO, Aorta; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (B and C, Courtesy American Society of Echocardiography.)

complete study routinely takes 30–60 minutes and if CHD is identified can last significantly longer. Application of cold ultrasound gel and environmental exposure may cause temperature instability. Applying pressure on the abdomen during subcostal imaging or extending the neck during suprasternal imaging may cause destabilization of the patient because of either cardiac or pulmonary compromise. Even in neonates, occasionally sedation is required to obtain a complete study.

Limitations of Neonatal Echocardiography

Although echocardiography is an extremely useful tool that has revolutionized the diagnostic evaluation of the neonatal cardiovascular system, it has a number of limitations:

- **Discrepancy between “echo-derived” and “catheter-derived” gradients.** Doppler echocardiography measures the peak instantaneous pressure difference at any point in time during flow across a stenotic valve. In the case of a stenotic aortic valve, this may occur during the upstroke of systole, not at the peak of systole. Catheter-based measures of pressure are taken at the peak of systole; hence, echo-derived pressure gradients do not equal, and usually exceed, catheter-derived measures. This discrepancy does not invalidate the measures of either modality but rather highlights the point that they are measures of gradients occurring during two different points in systole. Historically, clinical decision making has been based on catheter-derived information; therefore echocardiographically derived data should be interpreted in this light. Other factors that may have an impact on differences in echocardiographic versus catheter-based gradients are level of sedation, hydration status, medications (inotropes), and ventilatory strategy.
- **Inadequate visualization of structures.** Lung disease can cause acoustic impedance, limiting the ability to visualize structures. Air within the thorax caused by air trapping, pneumothorax, or pneumopericardium can result in a dramatic deterioration in image clarity.
- **Inadequate Doppler signal for velocity measurement.** Small blood volumes traveling at low velocity may be difficult to identify with echocardiography. Examples are coronary arteries in the very small, premature infant and pulmonary vein flow in patients with severe lung disease in whom pulmonary blood flow may be limited. Identification of pulmonary venous anatomy and flow in infants treated with ECMO also may be difficult as a result of reduced pulmonary circulation. Transesophageal echocardiography (TEE) may be indicated in these patients because of the enhanced imaging resolution of this modality.

Fetal Echocardiography: Goals of Imaging

CHD, which refers mainly to anatomic malformations of the heart, constitutes one of the most common congenital anomalies. The reported incidence rate per 100 live-born infants is nearly 1 by the end of the first year of life (Bjornard et al., 2013). An interest in the prenatal detection of major congenital malformations, including CHD, has blossomed over the past two to three decades as technologic advances have improved image quality such that a complete anatomic assessment, including the screening views of the fetal heart, can be obtained in nearly all women by 18 weeks' gestation and in many late in the first trimester. Furthermore, prenatal detection rates have improved as obstetric societies have adopted guidelines for the comprehensive anatomic assessment of the mid-trimester fetus, including the fetal heart. The

TABLE 53.2

Indications for Fetal Echocardiography

| Maternal Indications | Fetal Indications |
|--|---|
| Family history of CHD, including prior child or pregnancy with CHD | Abnormal obstetric screening ultrasound |
| Metabolic disorders (e.g., diabetes) | Extra-cardiac abnormality |
| Exposure to teratogens | Chromosomal abnormality |
| Exposure to prostaglandin synthetase inhibitors (ibuprofen) | Arrhythmia |
| Infection (rubella, Coxsackie, parvovirus B19) | Hydrops |
| Autoimmune diagnosis (e.g., Sjögren syndrome, SLE) | Increased first-trimester nuchal translucency |
| Familial inherited disorder (Marfan, Noonan syndromes) | Multiple gestation and suspected twin-twin transfusion syndrome |
| In vitro fertilization | |

CHD, Congenital heart disease; SLE, systemic lupus erythematosus.

four-chambered view of the heart was included in the guidelines released in 2004 by the American Institute of Ultrasound in Medicine in conjunction with the American College of Radiology, American College of Obstetricians and Gynecologists, and the Society of Radiologists in Ultrasound; however, it was not until 2013 that the outflow tracts were identified as essential components (American Institute of Ultrasound in Medicine Practice Guideline, 2013).

Similar to neonatal echocardiography, fetal echocardiography is the mainstay of imaging the fetal cardiovascular system. Fetal echocardiography refers to a comprehensive cardiovascular evaluation in excess of the limited screening views obtained as part of the mid-trimester anatomic scan. A fetal echocardiogram is recommended in those with identified maternal or fetal risk factors (Table 53.2). However, the majority of CHD is identified in fetuses with no known risk factors. Despite this tiered approach, CHD continues to be one of the most frequently missed malformations, with reported rates consistently less than predicted.

The ultimate goal of fetal echocardiography is the accurate definition of any anatomic abnormality of the heart during the prenatal time period. Once a diagnosis is established, the secondary goal of fetal echocardiography, parental counseling, can begin. Complete parental counseling includes not only a discussion of the abnormality identified but also the increased risk for extra-cardiac anomalies and chromosomal abnormalities (if applicable), management strategy, and the long-term outcomes of those with an identified lesion. Prenatal management plans need to be discussed, including local laws regarding termination of a pregnancy. Finally, perinatal management plans can be created to smooth the transition to the postnatal time period. In the fetus identified with ductal-dependent CHD, prenatal detection has been shown to improve outcome by reducing postnatal acidosis, morbidity, and mortality (Tworetzky et al., 2001; Verheijen et al., 2001).

Fetal Imaging Techniques

Cardiac formation is complete by 8 weeks after conception, and ventricular contraction can be detected by ultrasound imaging at that time. The optimal timing for performance of a comprehensive transabdominal fetal echocardiogram is 18–20 weeks'

gestation; however, as resolution has improved, earlier diagnosis and reassurance may be possible late in the first trimester (Smrcek et al., 2006).

Similar to a pediatric transthoracic echocardiogram, a fetal echocardiogram involves assessing cardiac anatomy in a series of standard imaging planes. The components of a comprehensive evaluation are listed in Table 53.3, although not all may be visualized in every fetus at every examination. In addition, some lesions can evolve in utero. Initial imaging establishes fetal position in utero (vertex, breech, or transverse). Once fetal left and right are established, the fetal abdominal situs is confirmed as well as the position of the heart within the thorax. Although uncommon as a whole, CHD and abnormalities of laterality (heterotaxy syndrome) are commonly found together.

Further imaging follows in a less predictable and frequently nonsequential order, accepting the inability to position the fetus in a standard position as well as frequent movement throughout the examination. The cardiovascular system is evaluated, beginning below the diaphragm in the abdomen and ending at the thoracic

inlet as a series of imaging planes. The four-chamber view (Fig. 53.8) is the most important in a comprehensive examination of the fetal heart. In this view, cardiac position, size, rate and rhythm, and qualitative contractility can all be assessed. Additionally many congenital heart defects can be detected (Fig. 53.9). After a four-chamber view is obtained, attention turns to visualization of the left- and right-ventricular outflow tracts and an assessment of ventriculoarterial concordance. Establishing the origin of the main pulmonary artery from the right ventricle and the aorta from the left ventricle is mandatory. Finally, systemic and pulmonary venous return are evaluated.

Structures are evaluated in orthogonal imaging planes in order to form a composite picture of the heart, including any identified malformation. In addition to obtaining clear pictures of each structure, flow is evaluated with color Doppler and pulsed Doppler.

TABLE 53.3 Components of the Fetal Echocardiogram

| | |
|--------------------------------|---|
| Overview | Fetal number and position Stomach position and abdominal situs Cardiac position |
| Biometric examination | Cardiothoracic ratio Biparietal diameter and head circumference Femur length Abdominal circumference |
| Cardiac imaging | Four-color view LVOT RVOT Great arteries Three-vessel view Bicaval view Ductal arch Aortic arch |
| Doppler examination | Inferior and superior vena cava Pulmonary veins Ductus venosus Foramen ovale Atrioventricular valves Semilunar valves Ductus arteriosus Transverse aortic arch Umbilical artery Umbilical vein |
| Measurement data | Atrioventricular valve diameter Semilunar valve diameter Main pulmonary artery Ascending aorta Branch pulmonary arteries Transverse aortic arch Ventricular length Ventricular short-axis dimensions |
| Examination of rate and rhythm | M-mode study of atrial and ventricular wall motion Doppler examination of atrial and ventricular flow patterns |

LVOT, Left-ventricular outflow tract; RVOT, right-ventricular outflow tract.

• **Fig. 53.8** Four-Chamber View of a Normal Fetal Heart. All four chambers are visible, with relative symmetry in size between the ventricles and atria. The right ventricle is identified by the presence of the moderator band and increased myocardial trabeculations in comparison with the left ventricle. The descending aorta is seen directly behind the left atrium.

• **Fig. 53.9** Four-Chamber View of the Fetal Heart With Complex Congenital Heart Disease. There is a large ventricular septal defect as well as a large primum atrial septal defect. There is size discrepancy between the two ventricular chambers. This fetus was diagnosed with an unbalanced complete atrioventricular canal defect.

• **Fig. 53.10** The Fetal Heart Rate Is Documented Using Aortic Valve Doppler. The time between successive beats is measured and a heart rate per minute calculated.

Valve regurgitation and/or stenosis can be detected and valve leaflet motion observed. From 2D images, structures can be measured and compared with established norms for varying gestation ages. Once a comprehensive assessment of the cardiac anatomy is complete, the heart rate is documented (Fig. 53.10). The rate and rhythm of the fetal heart are evaluated by mechanical surrogate events, specifically the movement of atria and ventricles or blood flow across valves.

Limitations of Fetal Echocardiography

Many of the same limitations associated with pediatric echocardiography apply to fetal echocardiographic imaging, including inadequate Doppler assessment for velocity measurement and limited visualization of cardiac structures. In addition, there are a number of limitations unique to fetal echocardiography, including:

- *In utero physiology.* Fetal circulation precludes exclusion of persistency of the ductus arteriosus postnatally. In addition, it is difficult or impossible to exclude a secundum atrial septal defect (ASD) because of the fetal requirement for a patent foramen ovale. Preferential right-to-left flow across the PDA can make assessment for coarctation of the aorta very challenging unless there is severe arch hypoplasia.
- *Imaging limitations.* While there are some advantages to fetal imaging in that an unlimited number of planes can be utilized, potential disadvantages include evolving calcification of bony structures, early gestational age when cardiac structures are at the lower limits of resolution, and noncardiac anomalies that may complicate understanding of fetal cardiac anatomy and/or physiology (examples include diaphragmatic hernia and congenital cystic adenomatoid malformation or congenital pulmonary airway malformation).
- *Maternal body habitus.* Obesity prevalence in the United States is epidemic. This has resulted in an ever-increasing population of overweight pregnant women. Obesity complicates fetal cardiac imaging in that increasing distance and mass between the fetal heart and echo transducer reduces imaging resolution.
- *Evolution with time.* Prediction of the degree of postnatal cyanosis caused by pulmonary outflow obstruction (e.g., tetralogy of

• **Fig. 53.11** Color Doppler Image Obtained During Transesophageal Imaging in the Operating Room Preceding Surgical Closure of a Moderate-Sized Membranous Ventricular Septal Defect. The color signal is blue, indicating flow away from the transducer, in this case left-to-right. LA, Left atrium; LV, left ventricle; RV, right ventricle; VSD, ventricular septal defect.

Fallot) can be challenging given the normal elevation in downstream pulmonary artery pressure in the fetus. In addition, restriction at the atrial septum (e.g., hypoplastic left heart syndrome and dextro-transposition of the great arteries) and obstruction in the setting of total anomalous pulmonary venous return can prove difficult to predict. Fetal echo specialists have developed tools and techniques (e.g., maternal hyperoxygenation testing) that have resulted in improvement in our ability to predict early postnatal morbidity.

Other Cardiovascular Imaging Modalities

Transesophageal Echocardiography

Technologic advancements in miniaturization led to the development of tiny transducer housings with small footprints such that a transthoracic echocardiogram can be performed in even the most premature of infants. Similar technology allowed for the development of neonatal TEE, in which a transducer can be introduced into the esophagus, and technology is available that expands the size range for TEE such that premature infants weighing just over 1 kg can be safely imaged. TEE is helpful in elucidating structures in the posterior mediastinum, such as pulmonary veins, and in overcoming acoustic impediments at the surface such as air and bone (Randolph et al., 2002). Most importantly, TEE has allowed for imaging to take place during interventional procedures in the operating room or catheterization laboratory (Fig. 53.11). This eliminates the need to place a transducer directly on the chest or abdomen, thereby avoiding potential contamination of the operative field. Interventional procedures can be guided by TEE imaging, yielding immediate feedback to the proceduralist that has been well validated as a means of improving overall outcomes.

Intracardiac Echocardiography

Recently, ultrasound transducer technology has been incorporated into the tips of catheters, allowing for intracardiac imaging (Hijazi

• **Fig. 53.12** Side-by-Side Two-Dimensional and Color Doppler Imaging of a Large Secundum Atrial Septal Defect Obtained by Intracardiac Echocardiographic Imaging. The color signal is red and laminar, indicating low-velocity, left-to-right flow through the atrial septal defect. The right atrium is dilated in comparison with the left atrium because of the volume load on the right heart caused by this shunt lesion. ASD, Atrial septal defect; LA, left atrium; RA, right atrium.

et al., 2009). This is primarily of use in the cardiac catheterization laboratory during the percutaneous device closure of ASDs (Fig. 53.12). Although these catheters provide an additional imaging modality, the size of these catheters (8 French) precludes their use in the femoral veins of younger children and neonates.

Three-Dimensional Echocardiography

Integration of multiplanar image data into a real-time three-dimensional (3D) display has been a goal of echocardiography. The earliest methods required acquisition of data that then required offline 3D image rendering. Over the past several years systems have been made available that are capable of displaying “live” 3D echocardiographic images (Fig. 53.13). This has resulted in our ability to interpret data as they are being obtained, making possible real-time bedside feedback. 3D echocardiography allows for enhanced identification of spatial relationships and structural malformations (Marx and Su, 2007). 3D echocardiographic technology has been miniaturized such that it is now available in an adult-sized TEE transducer. This allows for the benefits of TEE

• **Fig. 53.13** Three-Dimensional Echocardiographic Image of a Pathologic Mitral Valve. Using this imaging technique, a view of the mitral valve position within the left ventricular cavity is obtained that allows for a more thorough understanding of the nature of the anomaly. In this case, the mitral valve is seen in a cross-sectional, short-axis view peering into the left-ventricular cavity. The mitral orifice is hypoplastic, resulting in obstruction to inflow. LV, Left ventricle; MV, mitral valve.

(improved image resolution and ease of image acquisition during procedures) to be combined with the enhanced data available from 3D imaging. In the foreseeable future, 3D TEE should be available in small transducers amenable to imaging the newborn and small child. 3D echocardiography will continue to evolve and promises to become an important modality as technologic advances continue.

Computed Tomography and Magnetic Resonance Imaging

While echocardiography remains the gold standard for the diagnosis of CHD, magnetic resonance imaging and computed tomography are increasingly serving as adjunctive imaging modalities, especially in cases where there are concerns regarding extra-cardiac vasculature (e.g., pulmonary artery branch pathology and aortic arch anomalies) (Sigal-Cinqualbre et al., 2011).

Summary

The echocardiographic assessment has become inseparable from effective management of the critically ill neonate. The ability to provide noninvasive real-time, bedside cardiac evaluation not only aids in the identification of congenital cardiac lesions but also, just as importantly, facilitates a thorough understanding of the current physiologic state. Pharmacologic, ventilatory, and surgical decision making are by necessity based on clarity surrounding how

these management strategies affect, and are affected by, cardiac status. In addition, the understanding of prenatal cardiac issues (e.g., anatomic anomalies, rhythm disturbances, myocardial function) can only be performed via fetal echocardiographic imaging. Neonatal outcomes are therefore dependent on both accurate fetal and postnatal echocardiographic diagnosis and the application of these data to overall multidisciplinary newborn care.
